Child Development

Child Development (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Blackwell Publishing, Inc., with offices at 350 Main Street, Malden, MA 02148, USA; 9600 Garsington Road, Oxford OX4 2ZG, UK; and 155 Cremorne St., Richmond VIC 3121, Australia. Blackwell Publishing, Inc., is now part of Wiley-Blackwell. Institutional Premium Subscription Rate (includes online access to current content and all online back files to January 1st 1997, where available): The Americas, $585; Rest of the World, £417. Premium Online-Only rates are also available (see below). Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

Customers in Canada should add 5% GST to the America rate or provide evidence of entitlement to exemption.

Customers in the UK and EU should add VAT at 7% to the rest of the World rate or provide a VAT registration number or evidence of entitlement to exemption.

For more information about Blackwell Publishing journals, including online access information, terms and conditions, and other pricing options, please visit www.blackwellpublishing.com or contact our customer service department, tel: (800) 835-6770 or + (781) 388-8599 (US office) +44 (0)1 865 778315 (UK office) or +65 6511 8000 (Asia Office). Subscription in 2008 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives*. Single issues from current and recent volumes are available at the current single issue price from Blackwell Publishing Journals. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org/cd.html. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. For information on full-text access, see www. blackwellpublishing.com.

Postmaster: Periodical postage paid at Boston, MA and additional offices. Mailing to the rest of the world by International Mail Express (IMEX). Canadian mail is sent by Canadian Publications Mail agreement number 40064709. Postmaster: Send all address changes to *Child Development*, Blackwell Publishing Inc., Journals Subscription Department, 350 Main St., Malden, MA 02148-5020.

For new orders, renewals, sample copy requests, claims, changes of address and all other subscription correspondences please contact the Journals Department at your nearest Blackwell office (address details listed above). UK office phone: +44 (0) 1865-778315, Fax: +44 (0) 1865-471775, Email: customerservices@blackwellpublishing.com; US office phone: 800-835-6770 or 781-388-8599, Fax: 781-388-8232, Email: customerservices@blackwellpublishing.com; Asia office phone: +65 6511 8000, Fax: +44 (0) 1865-471775, Email: customerservices@blackwellpublishing.com

Congruency as a Nonspecific Perceptual Property Contributing to Newborns' Face Preference

Viola Macchi Cassia
University of Milano-Bicocca

Eloisa Valenza, Francesca Simion, and Irene Leo
University of Padova

Past research has shown that top-heaviness is a perceptual property that plays a crucial role in triggering newborns' preference toward faces. The present study examined the contribution of a second configural property, *congruency,* to newborns' face preference. Experiments 1 and 2 demonstrated that when embedded in nonfacelike stimuli, congruency induces a preference of the same strength as that induced by facedness. Experiments 3 and 4 demonstrated that the attentional biases toward facedness *and* congruency produce a cumulative effect on newborns' visual preferences according to an additive model. These findings were extended by those of Experiment 5, showing that the additive model holds true when congruency is added to top-heaviness in nonfacelike stimuli displaying more elements in the upper portion.

Face recognition in human adults is considered to be a sophisticated and specialized ability. This is because faces are highly complex visual stimuli whose processing involves specific brain regions (Kanwisher, McDermott, & Chun, 1997; Sergent, Ohta, & MacDonald, 1992) and specialized perceptual strategies (see Peterson & Rhodes, 2003, for a review). This specialized response toward faces has sparked debates as to whether specialization may be innate and specific to faces (e.g., Farah, Rabinowitz, Quinn, & Liu, 2000) or may be acquired through the extensive experience individuals acquire with faces within the human species-specific environment (expertise hypothesis; Diamond & Carey, 1986; Gauthier & Tarr, 1997, 2002). Central to this debate is evidence provided by developmental literature showing that just a few days after birth, when visual experience with faces is still minimal, newborns' visual attention is preferentially attracted toward both schematic facelike configurations (Johnson & Morton, 1991; Mondloch et al., 1999; Valenza, Simion, Macchi Cassia, & Umiltà, 1996) and veridical face images (Macchi Cassia, Turati, & Simion, 2004), as compared to equally complex nonfacelike configurations.

There is little dispute that this initial attentional bias toward faces triggers the development of neurocognitive specialization for this class of stimuli, as it results in biased input being provided to the developing cortical tissues within the ventral visual cortex. As a benefit from their frequent exposure to faces, these cortical circuits become progressively structurally and functionally specialized for the processing of stimuli that fall within the face category (Johnson, 2000). Support for this view comes from studies on the effects of early visual deprivation. These studies show that when the face bias cannot exert its influence from birth, as in individuals born with dense bilateral cataracts, face recognition abilities follow an abnormal developmental trajectory (Geldart, Mondloch, Maurer, de Schonen, & Brent, 2002; Le Grand, Mondloch, Maurer, & Brent, 2001).

However, controversy remains about the basis of the newborns' face bias. According to the model of the development of face processing originally proposed by Johnson and Morton (1991) and more recently updated by Johnson (2005), newborns' attention is triggered by faces due to the rapid and automatic activation of a face-configuration detector (i.e., Conspec). This face detector is supported by a fast subcortical processing route operating on low-spatial frequencies, which selectively responds to stimuli consisting of a raised surface with darker areas corresponding to the approximate locations of eyes

and mouth. An alternative view, which has recently received much attention within the field, proposes that newborns' face preference arises from a number of domain-general perceptual biases that drive newborns' attention toward certain structural properties of visual stimuli (Simion, Macchi Cassia, Turati, & Valenza, 2001, 2003; Turati, 2004). It has been proposed that these nonspecific biases may likely derive from the functional properties of the newborn's visual system and have a priori nothing to do with faces. Rather, they are domain relevant, allowing newborns to successfully select faces among other nonfacelike stimuli within their species-typical environment.

This claim derives mainly from two lines of reasoning. First, it has been shown that in addition to facedness, newborns manifest spontaneous preferences for other structural properties of visual stimuli (Farroni, Valenza, Simion, & Umiltà, 2000; Simion, Valenza, Macchi Cassia, Turati, & Umiltà, 2002; Slater, Earle, Morison, & Rose, 1985). Therefore, facedness is not the only stimulus dimension that is capable of triggering infants' attention at birth. Second, faces themselves can be described as a collection of perceptual properties. Therefore, the possibility exists that some, if not each of these properties, plays a role in prompting the newborns' attentional response toward facelike stimuli.

Until now, research has focused on one of the structural properties embedded in faces, namely, "top-heaviness." Faces can be described as top-heavy stimuli because they display a greater amount of patterning—the eyes and eyebrows—in the upper portion, and a lesser amount—the mouth—in the lower portion. A series of studies have shown that when embedded in geometric nonfacelike stimuli, the top-heavy property is capable of inducing a preferential visual response in newborns (Simion et al., 2002). This preferential response has been related to a difference in sensitivity between the upper and the lower visual field, similar to the upper visual field advantage observed in adults (Rubin, Nakayama, & Shapley, 1996; Skrandies, 1987), which would render top-heavy patterns more easily detectable than other stimuli. The key finding from these studies, obtained using both schematic (Turati, Simion, Milani, & Umiltà, 2002) and veridical (Macchi Cassia et al., 2004) face images, is that newborns attend equally long to a face as to a perceptually similar nonface stimulus that shares with the face a top-heavy distribution of the features within the outer contour. This demonstration that the facelike arrangement of the inner features displayed by the face did not selectively affect newborns' visual behavior was taken as evidence that what is classically interpreted as a specific inborn preference for the face geometry is likely the result of a more general preference for top-heavy visual objects. Indeed, stimuli within this category include but are not limited to faces.

In the present study, we investigated the contribution to the face preference phenomenon of a second configural visual property included in faces, which we refer to as "congruency." Congruency can be defined, in any given pattern, by the presence of a congruent or corresponding relationship between the shape and the orientation of the bounded area delimiting the pattern and the spatial disposition of the included features. Although the congruency property could be much easily detected in abstract, geometric configurations than in realistic images of real-life visual objects, faces indeed can be described as congruent stimuli. Despite within-category variability in perceptual appearance, faces on average are delimited by a mono-oriented frame, which appears wider in the upper part where the hair and ears are located and narrower in the lower part where the chin and the neck are located. Therefore, given the typical spatial arrangement of the eyes and mouth, faces display a greater number of features in the widest portion and only one feature in the narrowest part. Following the same logic used in earlier studies investigating the contribution of the top-heavy bias to newborns' face preference, we reasoned that if the congruency property is capable of inducing a preferential response when embedded in nonfacelike configurations, then it could be argued that this property also plays a role in inducing newborns' preference for faces.

The hypothesis that congruent visual configurations may be preferred at birth over noncongruent patterns appears reasonable in light of three lines of research. First, there is considerable evidence that newborns are highly sensitive to configural–holistic properties emerging from the interrelations between the component parts of the stimuli. For instance, they can perceive the invariance of the spatial relationship between single features, which vary in their absolute position within an array (Antell, Caron, & Myers, 1985). Also, newborns are able to group separate sets of elements according to Gestalt principles (Farroni et al., 2000), and they find configural and global cues in hierarchical patterns more easily detectable than featural and local information (Macchi Cassia, Simion, Milani, & Umiltà, 2002). Second, based on Gestalt theories of visual perception (Garner, 1974; Palmer, 1991), in comparison to noncongruent configurations, congruent configurations provide a better fit for the criteria of figural simplicity and regularity that render visual patterns more easily and economically processed and represented by the human perceptual system. Because newborns have been shown to perceive and organize visual arrays according to Gestalt principles, such as lightness similarity (Farroni et al., 2000) and common motion (Valenza & Bulf, 2007), it seems reasonable to hypothesize that newborns may also be sensitive to other stimulus dimensions that contribute to figural goodness, such as symmetry, repetition, and regularity. Each of these dimensions is maximally present in congruent visual configurations. Third, preliminary findings from an exploratory visual preference study showed that when newborns were presented with a 180° rotated version of the schematic facelike and nonfacelike configurations used in earlier face preference studies, they did not show a preferential response for either of the two stimuli ($p = .2$; Macchi Cassia, Valenza, and Simion, unpublished data; Figure 1). A possible interpretation of this finding is that each of the stimuli contained a relevant property, that is, top-heaviness or congruency, and that these two properties competed in triggering newborns' attention. Indeed, being upside down, the schematic face displayed a congruent relationship between the orientation of the outer border and the spatial locations of the included elements (i.e., two elements were located in the widest portion of the border) in the absence of a top-heavy arrangement of those elements (i.e., two elements were located in the lower part of the triplet and one in the upper part). In contrast, the rotated nonfacelike stimulus displayed a noncongruent relation between the border and the inner elements in the presence of a top-heavy arrangement of those elements. Therefore, newborns may have failed to show a preference for either of the two stimuli as a consequence of the competing properties embedded in the stimuli.

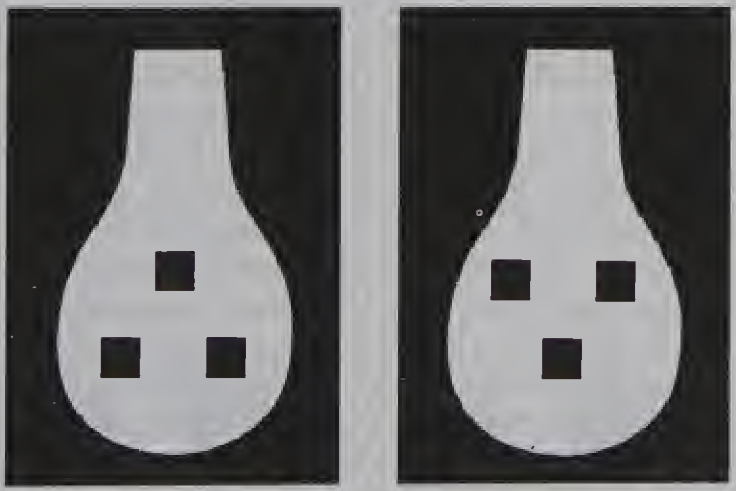

Figure 1. The 180° rotated version of the schematic facelike and nonfacelike configurations used in the exploratory visual preference study.

Note. Newborns did not show a preferential response for either of the two stimuli (Macchi Cassia, Valenza, and Simion, unpublished data).

In the present study, we aimed to test the role played by the perceptual property of congruency in newborns' face preference. To do so, we used the same approach that was used in previous studies investigating the role of the top-heavy property in newborns' face preference. The rationale of those studies was that of altering the spatial integrity of the facelike configuration so as to selectively break one of the structural rules embedded in faces and testing the effect of each manipulation on newborns' visual preferences. The same systematic approach of decomposing the structural properties defining facedness was applied in the present study, where we measured newborns' attentional responses to compound geometric stimuli in which we independently manipulated the facelike versus nonfacelike arrangement of the inner elements and the congruent versus noncongruent relation of the elements with the shape of the external contour. It is important to note that in the facelike stimuli used in Experiments 1 through 4, the facedness and the top-heavy property were inextricably mixed, and therefore, we refer to those stimuli as *facelike* and make reference to *facedness* as the crucial property defining those stimuli. In the stimuli used in Experiment 5, the number and shape of the inner elements and the spatial integrity of the facelike configuration were altered. Therefore, we refer to those stimuli as nonfacelike *top-heavy* and make reference to top-heaviness as the crucial property defining them.

In the five reported experiments, newborns were tested using a preferential looking paradigm. The specific aims of the experiments were (a) to determine whether the congruency property elicits a preference when it is embedded in nonfacelike stimuli (Experiment 1); (b) to test the relative strength of congruency and facedness in eliciting newborns' preference (Experiment 2); (c) to test the hypothesis of an additive model, where facedness and congruency contribute to the same extent to trigger newborns' attention toward faces (Experiments 3 and 4); and (d) to extend the validity of the additive model when congruency is added to top-heaviness in nonfacelike stimuli displaying more elements in the upper portion (Experiment 5).

Experiment 1

The aim of the first experiment was to provide evidence as to whether newborns show a spontaneous visual preference for congruent over noncongruent nonfacelike visual configurations. To test this hypothesis, newborns were presented with two compound stimuli comprising three black squares embedded in a triangular-shaped area. The orientation of the triangular-shaped areas was either congruent or noncongruent with the spatial arrangement of the inner elements (Figure 2). The spatial arrangement of the three squares was analogous to that used in the inverted nonfacelike stimuli employed in the studies of Johnson and Morton (1991) and Valenza et al. (1996), showing newborns' preference for schematic faces.

Method

Participants. The participants were 12 (5 males) healthy, full-term infants, 25–73 hr old, recruited from the maternity wards of the Pediatric Clinic at the University of Padova and the Gynecology Unit at the Hospital of Abano Terme. They were middle-class infants, and 99% of them were Caucasian and 1% was Asian. Two additional infants were tested, but one did not complete testing due to fussiness and one was excluded from the data analysis due to position bias (i.e., looking more than 80% of the time in one direction). Infants were tested only in an awake, alert state, after the parents had given their informed consent.

Stimuli. Each stimulus comprised three black square elements that were 2.2 cm (4.2°) on each side and located into a white triangular-shaped area that was 13.5 cm (24.2°) in width and 15 cm (26.6°) in height. The squared elements were arranged in a nonfacelike disposition, with two elements in the lower part and one in the upper part, so as to create a triangle with one vertex pointing up. The distance between the three elements was 1 cm (1.9°). The two stimuli were identical except for the orientation of the white area, which paralleled the orientation of the triangle created by the three inner elements with one vertex pointing up in the congruent stimulus, and rotated 180° so that the vertex was pointing down in the noncongruent stimulus (Figure 2).

Apparatus. The infant sat on a student's lap, in front of a black panel, at a distance of about 30 cm. The panel had two square holes where the black screens of two computer monitors appeared. The infant's eyes were aligned with a red flickering light emitting diode (LED), located in the center of the screen. The LED was used to attract the infant's gaze at the start of both the habituation and the preference test phases, subtended about 2° of a visual angle and, when turned on, blinked at a rate of 300 ms. Stimuli were projected bilaterally at a distance of approximately 7 cm from the central LED. To prevent interference from irrelevant stimuli, two black panels were placed on both sides of the infant to limit peripheral vision.

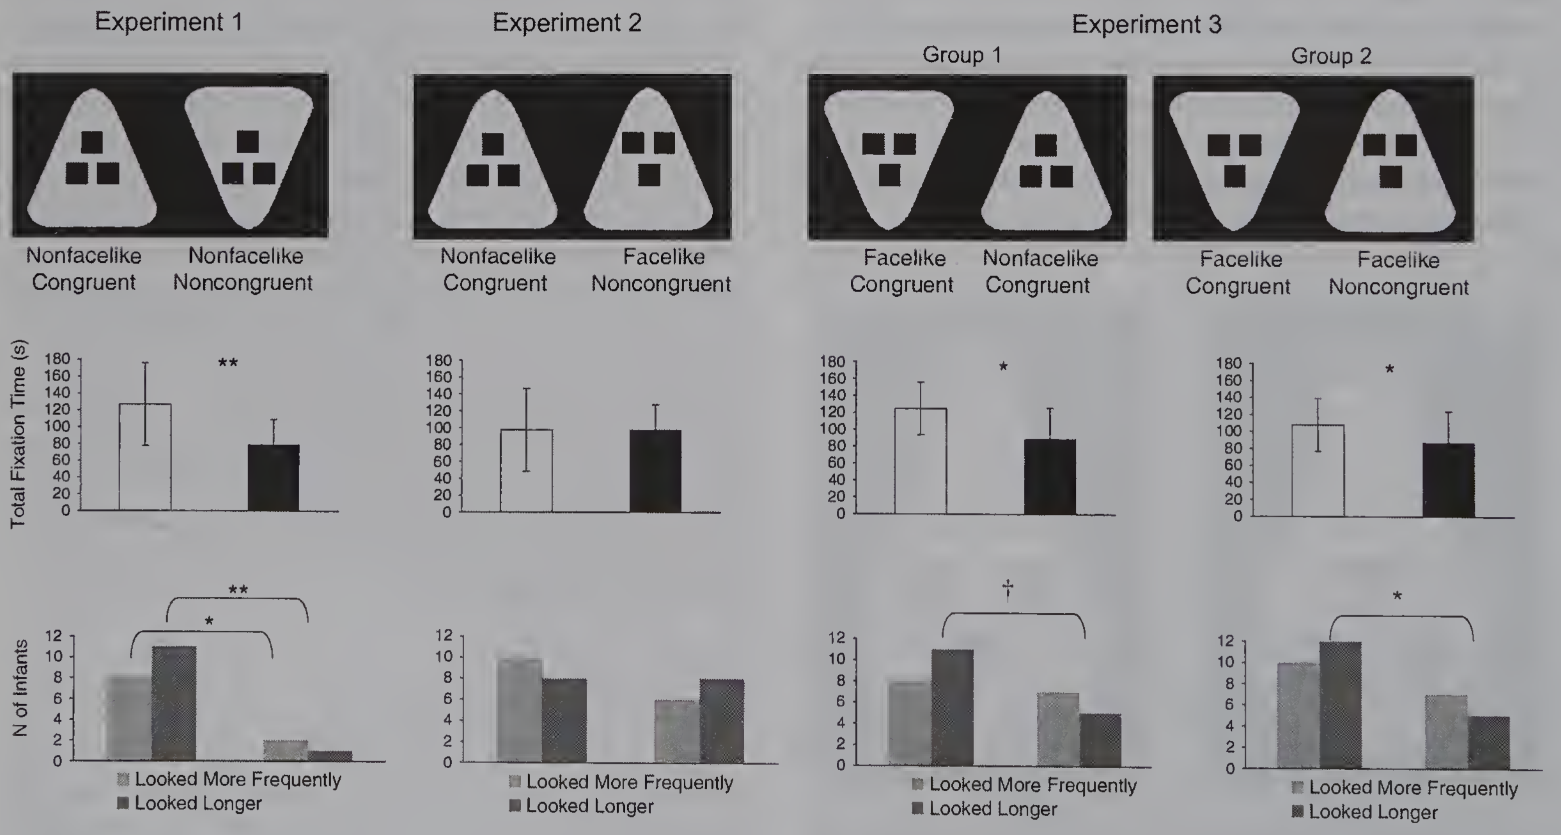

Figure 2. Stimulus pairs and results from Experiments 1, 2, and 3.

Note. For each experiment, two graphs are reported. The first graph shows the total fixation time toward each stimulus, with error bars indicating standard deviations. The second graph shows the number of newborns who oriented more frequently and/or looked longer toward each stimulus. For each graph, the *p* value is reported for the comparison between the stimuli.

$^*p < .05$. $^{**}p < .01$. $^\dagger p = .07$.

Procedure. Each trial began with the central flickering LED. As soon as the infant fixated the LED, an experimenter started the sequence of trials by pressing a key on the computer keyboard. This automatically turned off the central LED and activated the stimuli on the screens. Stimuli remained on as long as the infant fixated one of them (i.e., infant control procedure). When the infant shifted his gaze from the display for more than 10 s, the experimenter turned off the stimuli and the central LED automatically turned on. All infants were presented with two trials, in which the position of the stimuli was counterbalanced. All testing sessions were video recorded. Videotapes of eye movements throughout the trial were subsequently analyzed frame by frame to the nearest 40 ms by two coders, both unaware of the stimuli presented. The coders recorded number of orienting responses toward the stimuli and total fixation times, that is, the sum of all fixations (Cohen, 1972, 1973). Intercoder agreement (Pearson correlation) was .99 for total fixation time and .91 for discrete number of looks.

Results

Preliminary analyses of variance (ANOVAs) showed no significant main effects or interactions involving the within-subjects factor of trial (first or second) for either dependent variable. Therefore, two separated *t* tests for dependent samples were performed to compare number of orienting responses and total fixation time to the congruent and the noncongruent stimulus. Newborns showed a nonsignificant trend to orient more frequently to the congruent pattern ($M = 15.7$, $SD = 5.4$) rather than to the noncongruent pattern ($M = 12.6$, $SD = 6.3$), $t(11) = 1.76$, $p = .106$. This trend reached statistical significance for total fixation times, which were 22% longer to the congruent stimulus ($M = 126.8$ s, $SD = 49.2$) than to the noncongruent stimulus ($M = 78.9$ s, $SD = 30.0$), $t(11) = 3.42$, $p = .006$ (both tests were two-tailed; Figure 2).

Finally, we examined the data for individual infants and compared the number of infants who oriented more frequently and/or looked longer at the congruent stimulus than at the noncongruent stimulus. The comparisons were performed by means of two different statistical tests: a binomial test and a nonparametric Wilcoxon signed-rank test, which was used in consideration of the small sample numerosity. Eight of 10 infants (2 infants were not included in the count because they produced the same number of looks to the two stimuli) made a greater number of looks to the congruent stimulus (8 vs. 2, binomial test $p = .044$ and Wilcoxon test $p = .092$), and 11 of 12 infants looked longer at the congruent stimulus (11 vs. 1, binomial test $p = .003$ and Wilcoxon test $p = .012$; Figure 2). The difference in looking times for the two stimuli ranged from 11.9 to 147.7 s.

Discussion

The results showed that the presence of a congruent relation between the shape and the orientation of the bounded area delimiting the pattern and the spatial disposition of the included features is one of the stimulus properties that control newborns' visual preferences. The two stimuli used in the present experiment contained the same amount of visual information, displayed the same symmetrical configuration, and neither resembled a face in that the spatial disposition of the inner elements did not simulate the face geometry. Rather, the stimuli differed exclusively in the orientation of the triangular-shaped contour and, therefore, in the congruent versus noncongruent relation between the contour and the triplet of inner elements. Therefore, congruency can be regarded as the crucial factor that produced the observed preference.

This finding proves particularly relevant because it provides the first demonstration of the presence in newborns of a spontaneous attentional bias toward a configural/relational perceptual property, that is, a property emerging from the spatial interrelations among the stimulus components (Kimchi, 1992). Most crucially, the demonstration that the congruent relation between the disposition of the inner elements and the shape of the external contour is capable of triggering newborns' attention when embedded in nonfacelike configurations raises the possibility that this same property may also play a role in triggering newborns' attention toward facelike stimuli. The spontaneous preference for the congruency property may be a contributing factor that, interacting with other factors, gives rise to the newborns' face preference phenomenon. This possibility was explored in the following experiments.

Experiment 2

To explore the strength of the congruency property in prompting newborns' attentional responses to facedness, in Experiment 2, the nonfacelike congruent stimulus preferred in Experiment 1 was contrasted to a noncongruent stimulus displaying a facelike arrangement of the inner elements (Figure 2). The facelike spatial arrangement of the triplet of elements in the noncongruent stimulus was analogous to that used in the upright facelike stimuli employed in the studies of Johnson and Morton (1991) and Valenza et al. (1996), showing newborns' preference for schematic faces. A preference for either of the two stimuli would indicate which of the two stimulus properties (i.e., facedness vs. congruency) is more influential in driving newborns' attention. Crucially, if newborns would not manifest a preference, this would imply that none of the two properties is more powerful than the other in triggering attentional responses at birth.

Method

Participants. The final sample consisted of 16 (10 males) healthy, full-term, middle-class, Caucasian infants, 24–79 hr old. Four additional infants were tested but not included in the sample because of fussiness ($n = 2$) or position bias ($n = 2$).

Stimuli. The stimuli in this experiment were the congruent nonfacelike pattern presented in Experiment 1 and a noncongruent facelike pattern, which was matched to the congruent pattern for the orientation of the white area and differed exclusively for the spatial disposition of the three inner elements (Figure 2). In both stimuli, the triangular-shaped white area had one vertex pointing up. In the facelike stimulus, two elements of the triplet were located in the upper part of the configuration and one in the lower part, whereas in the nonfacelike stimulus, the triplet of elements was rotated 180° so that two elements appeared in the lower part and one in the upper part.

Apparatus and procedure. The same apparatus and procedure from Experiment 1 were used.

Results

Preliminary ANOVAs showed no significant main effects or interactions involving the within-subjects factor of trial (first or second) for either dependent variable. Two paired-sample *t* tests were performed to determine whether newborns' number of orienting responses and total fixation time differed for the two stimuli presented. The difference was not significant for either dependent variable (Figure 2). Newborns looked 14.9 ($SD = 6.7$) times at the noncongruent facelike stimulus and 16.2 ($SD = 9.3$) times at the congruent nonfacelike stimulus, $t(15) = 1.26, p = .226$. Similarly, they spent 96.2 s ($SD = 42.0$) and 97.5 s ($SD = 60.9$) looking at the noncongruent and congruent stimuli, respectively, $t(15) = 0.07, p = .946$ (both tests were two-tailed). Finally, examination of the data for individual infants revealed that the number of infants who produced a greater number of looks and/or looked longer at the noncongruent facelike stimulus did not differ from the number of infants who oriented more frequently toward (6 vs. 10, binomial test $p = .122$ and Wilcoxon test $p = .242$) and/or fixated longer (8 vs. 8, binomial test $p = .196$ and Wilcoxon test $p = .717$) the congruent nonfacelike stimulus (Figure 2). The difference in looking times for the two stimuli ranged from 14.8 to 171.7 s.

Discussion

Although nonsignificant results should be interpreted with caution, these findings seem to suggest that facedness per se was not the only factor affecting newborns' preferences in the present experiment. The absence of a preference for either stimulus likely indicates that facedness and the configural property of congruency contributed to the same extent to drive newborns' preferences. These findings confirm and extend the null results obtained in the exploratory study with 180° rotated schematic facelike and nonfacelike stimuli (Macchi Cassia, Valenza, and Simion, unpublished data; Figure 1), providing further evidence that when facedness and congruency are pitted against each other, these two stimulus properties evoke a competition for newborns' attentional resources. The result is a failure for newborns to show a preference for either stimulus.

The demonstration that the preference for the congruent stimulus was not overcome by the preference for the facelike stimulus lands support to the hypothesis that both stimulus properties—congruency and facedness—may play a role in inducing newborns' preference for faces, given that both are properties defining the face stimulus category. More specifically, the lack of any significant result in Experiment 2 might support the hypothesis that the attentional biases toward facedness and congruency produce a cumulative effect on newborns' visual preferences according to an additive model, in which both biases would exert an equally critical influence on newborns' preferential responses.

Experiment 3

The aim of Experiment 3 was to provide a direct test of the additive role of facedness and congruency in inducing newborns' preferences. Two different groups of infants were tested, each presented with a pair of stimuli that were equated for one of the two properties and differed for the presence versus absence of the other property. For Group 1, both stimuli within the pair preserved a congruent relation between the inner elements and the outer frame, and only one of the stimuli displayed the facelike arrangement of the inner elements that defines facedness. For Group 2, both stimuli displayed the facedness property, and only one of the two displayed a congruent relation between the inner elements and the outer frame (Figure 2). Based on the evidence provided by Experiment 2, we hypothesized that the attentional biases toward the two stimulus properties of facedness and congruency may exert a cumulative influence on newborns' visual preferences, according to an additive model. Based on this hypothesis, we predicted that both groups of infants would prefer the stimulus in which both properties were present over the stimulus in which only one of the two properties was present. The alternative hypothesis, according to which the facelike disposition of the three inner elements that produces facedness, per se, is sufficient to trigger newborns' attention toward faces (Johnson & Morton, 1991), would predict that no preference should be found for Group 2, whereas a preference for the facelike congruent stimulus should be found for Group 1.

Method

Participants. The final sample consisted of 33 (14 males) healthy, full-term infants, 30–65 hr old, randomly assigned to two groups (16 in Group 1 and 17 in Group 2). Participants were middle-class infants, and 92% of them were Caucasian, 1% African, and 7% Asian. Ten additional infants were tested but not included in the sample due to position bias ($n = 1$) or experimenter error ($n = 1$), or because they did not complete testing due to fussiness ($n = 8$).

Stimuli. Two different pairs of stimuli of the same type as those used in Experiments 1 and 2 were employed, one for each group of participants. Each pair comprised a congruent facelike stimulus in which both the stimulus properties of facedness and congruency were present, and a stimulus similar to the previous one in which the facedness property (Group 1) or the congruency property (Group 2) was selectively removed. Therefore, in the first pair of stimuli (Group 1), the congruent facelike stimulus was contrasted with a congruent nonfacelike stimulus, whereas in the second pair (Group 2), the congruent facelike stimulus was contrasted with a noncongruent facelike stimulus (Figure 2). As in Experiments 1 and 2, the facelike versus nonfacelike appearance of the stimuli was produced by a 0° versus 180° rotation of the triplet of inner elements, and the congruent versus noncongruent nature of the stimuli was a product of the rotation of the triangular-shaped white area in which the elements were comprised.

Apparatus and procedure. The apparatus and procedure were the same as those used in Experiment 1.

Results

Preliminary ANOVAs showed a significant main effect of the within-subjects factor of trial (first or second) for total fixation times, $F(1, 31) = 10.27$, $p = .003$, due to newborns producing longer fixation times in the first trial compared to the second trial. However, no significant interactions involving the factor of trial were found for either dependent variable. Therefore, two ANOVAs with group (Groups 1 and 2) as a between-subjects factor and stimulus properties (two properties and one property) as a within-subjects factor were performed, one for number of orienting responses and the other for total fixation time. No significant effects emerged for number of orienting responses. Newborns in Group 1 looked 13.1 ($SD = 4.4$) times at the congruent facelike stimulus and 11.8 ($SD = 5.0$) times at the congruent nonfacelike stimulus, $t(15) = 0.86$, $p = .401$, and newborns in Group 2 looked 11.7 ($SD = 6.2$) times at the congruent facelike stimulus and 10.4 ($SD = 4.4$) times at the noncongruent facelike stimulus, $t(16) = 0.91$, $p = .379$. For total fixation time, there was a main effect of stimulus properties, $F(1, 31) = 10.27$, $p = .003$, due to fixation times to the congruent facelike stimulus being longer than fixation times to the second stimulus of the pair for each group. For Group 1, fixation times were 18% longer for the congruent facelike stimulus ($M = 124.7$ s, $SD = 40.5$) than for the congruent nonfacelike stimulus ($M = 89.0$ s, $SD = 39.7$), $t(15) = 2.29$, $p = .037$. For Group 2, the facelike congruent stimulus was fixated 11% longer ($M = 108.0$ s, $SD = 31.1$) than the facelike noncongruent stimulus ($M = 87.3$ s, $SD = 36.6$), $t(16) = 2.36$, $p = .031$ (all tests were two-tailed; Figure 2).

Examination of the data for individual infants revealed that for Group 1, the number of infants who produced a greater number of looks at the congruent facelike stimulus did not differ from the number of infants who oriented more frequently toward the congruent nonfacelike stimulus (8 vs. 7, binomial test $p = .196$ and Wilcoxon test $p = .348$), with one infant not included in the count because he or she made the same number of looks to the two stimuli. The number of infants who looked longer at one or the other stimulus was only marginally significant (11 vs. 5, binomial test $p = .067$ and Wilcoxon test $p = .063$). For Group 2, 10 of 17 infants oriented more frequently toward the congruent facelike stimulus compared to the noncongruent facelike stimulus (10 vs. 7, binomial test $p = .148$ and Wilcoxon test $p = .651$), and 12 of 17 looked longer at this same stimulus (12 vs. 5, binomial test $p = .047$ and Wilcoxon test $p = .035$; Figure 2). For both groups, the differences in looking times for the two stimuli ranged from 3.8 to 111.3 s.

Discussion

Results from Experiment 3 showed that newborns manifested a spontaneous visual preference for stimuli in which both the facedness and the congruency properties were present over stimuli that comprised only one of these two properties. Specifically, evidence from Group 1 showed that the strength of congruency in triggering newborns' attention increased when this property was accompanied by facedness. Evidence from Group 2 showed that facedness per se was not sufficient to preferentially attract newborns' attention and that the attention-triggering value of the facelike arrangement of the inner elements was enhanced when the elements maintained a congruent relation with the external frame. This finding does not support the hypothesis of the existence at birth of a Conspec-like mechanism, which would be automatically activated by stimuli displaying the unique geometry of the face, defined by the correct relative location of the internal features for the eyes and mouth (i.e., facedness; Johnson & Morton, 1991; Johnson, 2005). Rather, the present findings are in line with recent claims that a number of attentional biases toward nonspecific stimulus properties combine to produce the face preference and demonstrate that the congruency bias is one of those biases (Simion et al., 2001, 2003).

Results from Experiment 3 demonstrate that the attentional biases toward facedness and congruency have an additive effect in driving newborns' preferences. The finding that the congruent facelike stimulus was preferred over both the congruent nonfacelike (Group 1) and the noncongruent facelike (Group 2) stimuli provide further support to the interpretation of the null results of Experiment 2. In fact, the two stimulus properties of facedness and congruency were capable of triggering newborns' attention to the same extent in the two groups, and their cumulative influence on newborns' visual preferences followed an additive rule. This finding provides support for the argument that both attentional biases toward facedness and congruency are involved in the preferential responses that newborns manifest for schematic faces.

One final note of caution concerns the evidence emerging from Group 2, showing that facedness did not exert an all-or-nothing influence on newborns' attention. This evidence derives from the comparison between two facelike stimuli, one displaying a congruent relation between the inner elements and the outer frame and the other in which the congruency property was not only missing but also intentionally violated by the misorientation of the outer frame. It is possible that the reduction of the figural goodness of the stimulus induced by this violation, rather than the cumulative effect produced by both the facedness and the congruency properties of the comparison stimulus, may have driven the preference for the congruent facelike stimulus observed in Group 2. If true, it could be hypothesized that if the congruent facelike stimulus was compared to a facelike stimulus in which the congruency property was neutralized, rather than violated, the facedness property would trigger newborns' attention to the same extent in both stimuli. This possibility was tested in Experiment 4.

Experiment 4

Experiment 4 was aimed at testing whether the preference observed in Group 2 of Experiment 3 would still be obtained when the congruent facelike stimulus is compared to a facelike configuration in which the triplet of inner elements is surrounded by a nonoriented, squared-shaped contour (Figure 3). If the congruent facelike stimulus was preferred in Experiment 3 because it included the two preferred properties of facedness and congruency, this preference should be maintained in Experiment 4. If, in contrast, the preference for the facelike congruent stimulus in Experiment 3 was a by-product of the reduced perceptual appeal produced by the violation of the congruency property in the stimulus to which it was compared, no preference should be expected in the present experiment.

Method

Participants. The final sample consisted of 15 (9 males) healthy, full-term, Caucasian infants, 25–80 hr old. Two additional infants were tested but not included in the sample due to position bias ($n = 1$) or fussiness ($n = 1$).

Stimuli. The stimuli in this experiment were the facelike congruent configuration presented in Experiment 3 and a facelike neutral stimulus in which the three squared elements were comprised within a white rectangular-shaped area whose width (24.2°) and height (26.6°) were the same as those of the triangular-shaped area surrounding

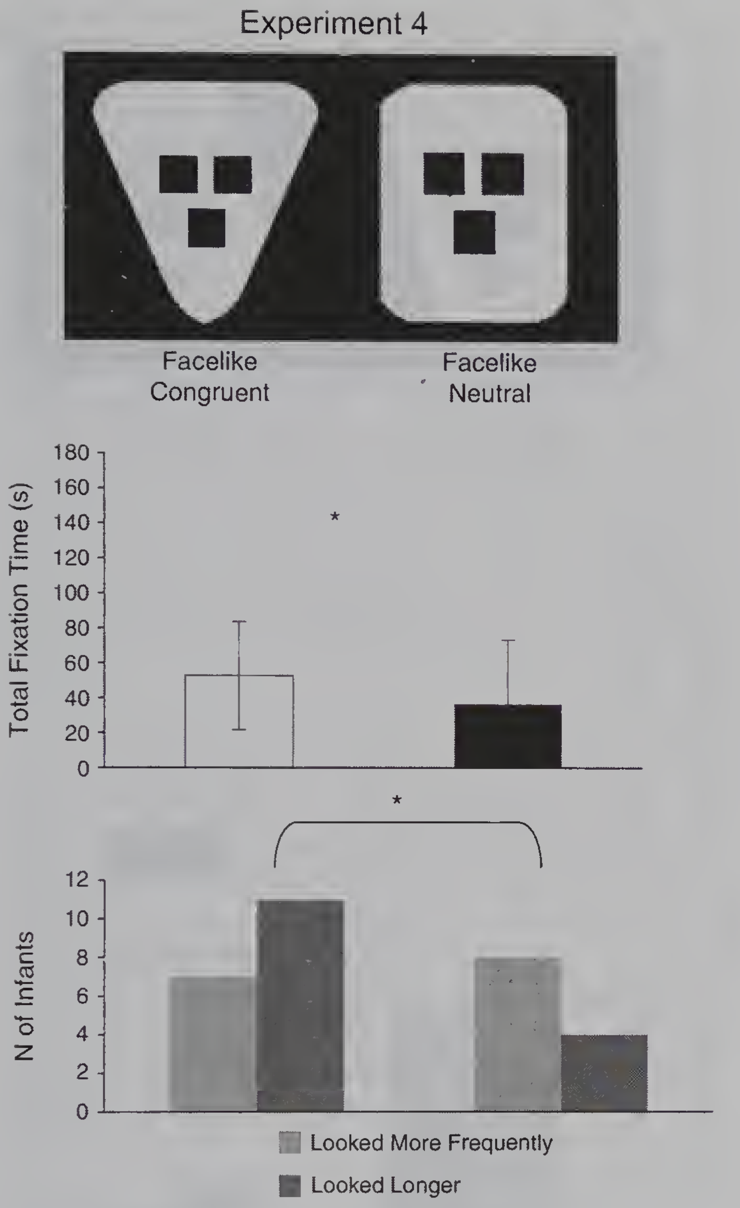

Figure 3. Stimulus pairs and results from Experiment 4.
Note. The first graph shows the total fixation time toward each stimulus and the second shows the number of newborns who oriented more frequently and/or looked longer toward each stimulus. The p values refer to the comparison between the stimuli, and the error bars indicate standard deviations.
$^*p < .05$.

the inner elements in the facelike congruent stimulus (Figure 3).

Apparatus and procedure. The apparatus and procedure were the same as those used in Experiment 1.

Results

Preliminary ANOVAs showed a significant main effect of the within-subjects factor of trial (first or second) for total fixation times, $F(1, 14) = 10.08$, $p = .007$, due to fixation times being longer during the first trial compared to the second trial, but no significant interactions involving this factor were found for either dependent variable. Therefore, two separated t tests for dependent samples were performed to compare number of orienting responses and total fixation time to the two stimuli presented. No difference was found for number of orienting responses. Newborns looked 15.5 ($SD = 5.8$) times at the facelike congruent stimulus and 14.1 ($SD = 6.6$) times at the facelike neutral stimulus, $t(14) = 0.70$, $p = .495$. In contrast, fixation times were 20% longer to the facelike congruent stimulus ($M = 52.7$ s, $SD = 24.9$) than to the facelike neutral stimulus ($M = 36.6$ s, $SD = 18.2$), $t(14) = 2.31$, $p = .037$ (Figure 3).

Examination of the data for individual infants showed that almost half of the infants in the sample oriented more frequently toward the facelike congruent stimulus (7 vs. 8, binomial test $p = .196$ and Wilcoxon test $p = .733$), whereas two thirds of the infants looked longer at this same stimulus (11 vs. 4, binomial test $p = .042$ and Wilcoxon test $p = .061$; Figure 3). The differences in looking times for the two stimuli ranged from 1.6 to 68.0 s.

Discussion

The results showed that the preference for the congruent facelike stimulus persevered when this stimulus was contrasted to a facelike stimulus in which the congruency property was neutralized by the presence of a nonoriented external contour. This finding demonstrates that the preference for the congruent facelike stimulus over the noncongruent facelike stimulus observed in Experiment 3 was truly due to the cumulative effect of the facedness and congruency properties. Moreover, this finding replicates and extends the results of Experiment 3, showing that the facedness property is capable of eliciting a preferential response only when the congruency property is concurrently present within the stimulus.

By replicating the findings of Experiment 3, the results of Experiment 4 provided further evidence for the additive effect exerts by congruency and facedness on newborns' visual preferences. The demonstration that the attentional biases toward these two stimulus properties produce a cumulative effect on newborns' visual preferences according to an additive model is in agreement with the claim that newborns' face preference derives from the cumulative action of a set of attentional biases toward different nonspecific stimulus properties that faces share with other nonface stimuli, rather than from one single specific bias toward facedness (Simion et al., 2001, 2003). However, this claim would receive much stronger support by the demonstration that the same cumulative effect on newborns' preferences could be found with congruent stimuli in which facedness is not confounded with top-heaviness. In fact, it is important to highlight that the nonspecific structural property of top-heaviness was inherently embedded in the facelike stimuli used in Experiments 3 and 4. Therefore, top-heaviness may have played a critical role in triggering newborns' preferences toward these stimuli. Using top-heavy stimuli displaying a nonfacelike disposition of the inner elements, in Experiment 5, we tested the hypothesis that the two perceptual properties of congruency and top-heaviness produce a cumulative effect on newborns' preferences.

Experiment 5

Experiment 5 was aimed at extending the results obtained for Group 2 of Experiment 3 to top-heavy stimuli that do not display the facelike arrangement of the inner elements, which defines facedness. Specifically, the goal was to provide direct evidence concerning the additive effect of the top-heavy bias and the congruency bias in driving newborns' preferences. Newborns were presented with a pair of compound stimuli comprising five elements, which were arranged so as to create a top-heavy nonfacelike configuration. Specifically, the elements were more numerous in the upper part compared to the lower part but not disposed in correct location for the eyes and mouth, as it was in the schematic facelike stimuli used in Experiments 2 through 4. Although being equated for the top-heavy configuration of the elements, the two stimuli differed for the orientation of the white area surrounding them, which was congruent with the spatial arrangement of the elements in one stimulus and incongruent with those elements in the second stimulus (Figure 4).

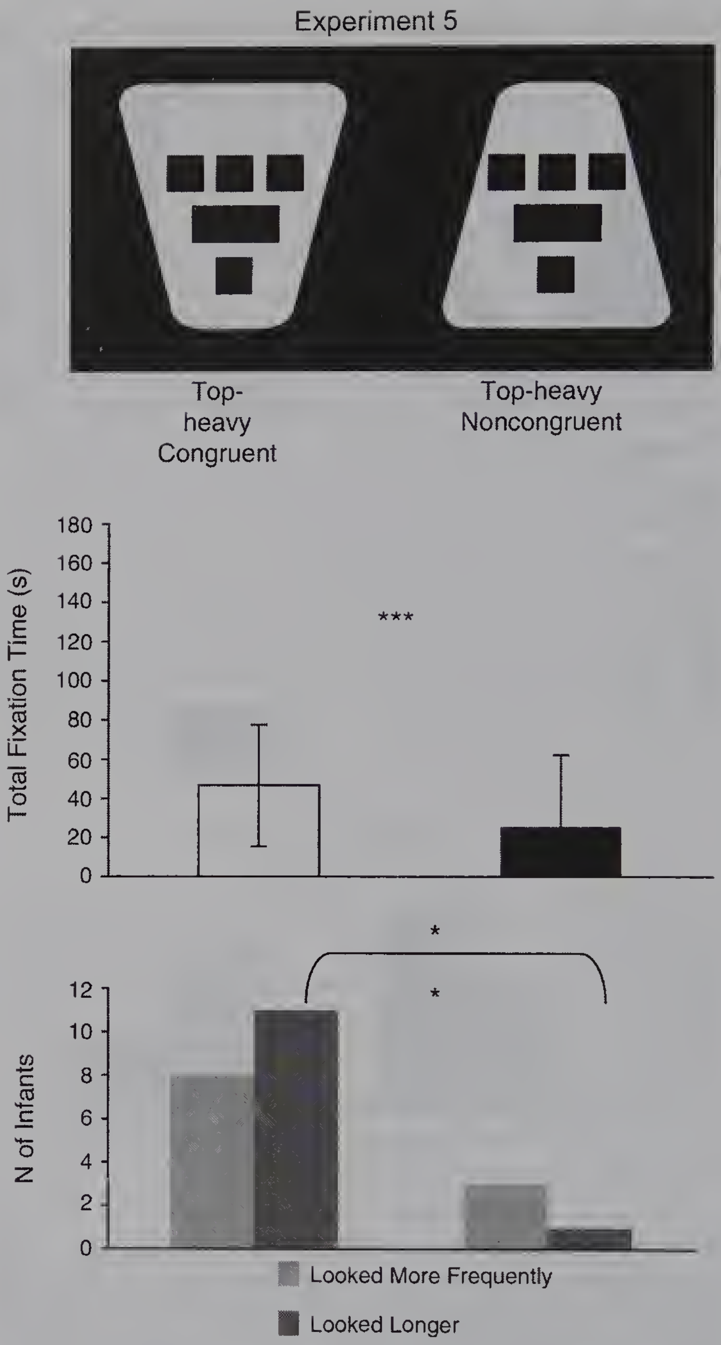

Figure 4. Stimulus pairs and results from Experiment 5.
Note. The first graph shows the total fixation time toward each stimulus and the second shows the number of newborns who oriented more frequently and/or looked longer toward each stimulus. The p values refer to the comparison between the stimuli, and the error bars indicate standard deviations.
$^{*}p < .05$. $^{***}p < .001$.

Method

Participants. The final sample consisted of 12 (7 males) healthy, full-term newborn infants, 27–82 hr old. Participants were middle-class infants, and 98% of them were Caucasian and 2% Asian. Two additional infants were tested but not included in the sample due to fussiness.

Stimuli. Each stimulus comprised four black square elements of the same size as those composing the stimuli used in Experiments 1 through 4 and one rectangular-shaped element that was 2.2 cm (4.2°) high and 5.9 (11.2°) wide. The distance between the elements was 1 cm (1.9°). Three of the four squared elements were located in the upper part of the stimulus, and only one was located in the lower part, with the rectangular-shaped element located in the middle, so as to create a top-heavy configuration. The elements were located into a white area, which differed in shape but not in size from that used in Experiments 1 through 4. The orientation of the white area paralleled the top-heavy distribution of the elements in the congruent stimulus and rotated 180° on the noncongruent stimulus (Figure 4).

Apparatus and procedure. The apparatus and procedure were the same as those used in Experiment 1.

Results

Preliminary ANOVAs showed no significant main effects or interactions involving the within-subjects factor of trial (first or second) for either dependent variable. Therefore, two paired-sample t tests were performed to determine whether newborns' number of orienting responses and total fixation time differed for the two stimuli presented. Newborns showed a marginally significant trend to orient more frequently to the top-heavy congruent stimulus ($M = 10.1$, $SD = 3.1$) rather than the top-heavy noncongruent stimulus ($M = 8.2$, $SD = 3.5$), $t(11) = 1.88$, $p = .089$. This trend reached statistical significance for total fixation times, which were 29% longer to the top-heavy congruent stimulus ($M = 46.6$ s, $SD = 12.7$) than to the noncongruent stimulus ($M = 25.6$ s, $SD = 9.8$), $t(11) = 5.21$, $p < .001$ (both tests were two-tailed; Figure 4).

Examination of the data for individual infants showed that only two thirds of the infants in the sample oriented more frequently toward the top-heavy congruent stimulus (8 vs. 3, binomial test $p = .081$ and Wilcoxon test $p = .107$), with one infant not included in the count because he or she made the same number of looks to the two stimuli, and almost all the infants looked longer at the same stimulus (11 vs. 1, binomial test $p = .003$ and Wilcoxon test $p = .004$; Figure 4). The differences in looking times for the two stimuli ranged from 4.9 to 40.5 s.

Discussion

The results showed that the top-heavy congruent stimulus was preferred over the top-heavy noncongruent stimulus, thus indicating that the congruency and top-heavy properties have an additive effect on newborns' preferences. When compared to the results obtained for Group 2 of Experiment 3, the findings from the present experiment suggest that the presence of the congruency property is crucial in determining the preference for top-heavy configurations in the same way as it is crucial for the emergence of the preference for schematic facelike configurations.

General Discussion

The results of the present study extend our knowledge concerning the stimulus properties capable of eliciting spontaneous visual preferences at birth (see Slater, 1995, for a review). Evidence from Experiment 1 shows that when two stimuli for which no preference has been shown to exist at birth are equated for the quantity of energy they contain (i.e., number of elements, contrast information), a configural property emerging from the spatial relations among the stimulus components (Kimchi, 1992) can induce a visual preference in newborns. This finding adds to other evidence showing that newborns manifest a preference for stimuli displaying specific distributions of energy within the pattern (i.e., specific structural properties), such as that for horizontal over vertical configurations (Farroni et al., 2000; Slater & Sykes, 1977; Slater et al., 1985) and for top-heavy patterns over bottom-heavy patterns (Simion et al., 2002). Together, these findings demonstrate that newborns are sensitive to stimulus dimensions other than those specified by physical, low-level properties (i.e., contrast information, spatial frequencies; Banks & Ginsburg, 1985; Banks & Salapatek, 1981).

Crucially, these findings are the first to demonstrate that newborns are sensitive to a configural, relational property generated by the interdependency among different features of the stimulus—the shape/orientation of the outer frame and the spatial relation among the inner features. In fact, to prefer the congruent pattern over noncongruent pattern in Experiment 1, and in the other experiments, newborns must not only organize the three squared blobs in a triangular configuration but also perceive the relationship between the triangular configuration of the internal elements and the orientation of the external frame. Therefore, overall the present findings demonstrate that newborns are sensitive to the relation between inner and outer features of the stimulus and appreciate the redundancy and regularity of this relation, independently of the facelike or nonfacelike appearance of the stimulus. Notably, with regard to faces, the presence since birth of the basic ability to extract the perceptual attributes of the relation between the inner and the outer features of the stimulus does not prevent infants from treating these features as independent cues for individual face recognition until around 7 months of age, when holistic processing of internal and external facial features has been found to first emerge (Cashon & Cohen, 2004; Schwarzer, Zauner, & Jovanovic, 2007).

Just as for preferences based on the physical properties of stimuli (Banks & Ginsburg, 1985; Banks & Salapatek, 1981), stimulus preferences based on the energy distribution within the pattern have been interpreted as resulting from constraints on the newborns' visual system, which would render some stimuli more easily detectable and explored than others. For example, newborns' preference for horizontal configurations over vertical configurations has been attributed to eye movements, which at birth tend to be greater in number and size in the horizontal, rather than the vertical direction (Slater & Sykes, 1977). Similarly, as already mentioned, newborns' preference for top-heavy configurations over bottom-heavy configurations has been related to a possible difference in sensitivity between the two vertical hemifields, which would parallel that observed in adults (Rubin, Nakayama, & Shapley, 1996; Skrandies, 1987). Evidence deriving from a neural network simulation study conducted by Acerra, Burnod, and de Schonen (2002) suggests that a similar interpretation based on constraints on the newborns' visual system may also apply to the preference for congruent stimuli over noncongruent stimuli. In comparison to noncongruent patterns, the regular disposition of the internal elements with respect to the shape of the outer contour in congruent patterns would provide a better fit for the tuning response properties of neurons in Area V1. These tuning properties, together with the limitations of the immature newborns' contrast sensitivity function, may act as a general perceptual filtering and amplification device, which would give congruent stimuli an attention-triggering advantage over noncongruent stimuli due to the regularity of the element position within the outer frame.

In addition to its relevance to the understanding of newborns' visual perceptual organization, the demonstration that the congruency property is capable of inducing visual preferences at birth in both facelike and nonfacelike stimuli is critical to the interpretation of the newborns' face preference phenomenon. Congruency is one of the perceptual properties contributing to the unique perceptual appearance of faces and facelike stimuli, together with top-heaviness. Overall, the results of the present study provide empirical support for this claim in two ways. First, Experiments 2, 3, and 4 demonstrated that the congruency property is necessary for the preference for facelike stimuli to manifest. Second, evidence from Experiment 5 showed that the copresence within a stimulus of the congruency and top-heavy perceptual properties produces a cumulative effect on newborns' visual preferences, which seems to be not dissimilar from the cumulative effect observed when congruency adds to facedness (Group 2 of Experiment 3).

More specifically, results of Experiments 1 and 2 show that the congruency property was capable of inducing a preferential response, which was not overcome by the preference for the facelike arrangement of the inner elements. Evidence from Experiment 3 demonstrates that the two stimulus properties have an additive effect on newborns' preferences. The key finding from this experiment is that, as already suggested by the results of Experiment 2, facedness and congruency have the same strength in triggering visual attention at birth and contribute to the same extent to the preference that newborns manifest for schematic facelike stimuli. This finding was further strengthened by the results of Experiment 4, where a congruent facelike pattern was preferred over a facelike pattern surrounded by a neutral, nonoriented contour. This evidence suggests that what is crucial in determining newborns' preference for schematic faces is not just the presence of a high-contrast contour surrounding the facelike arrangement of the inner elements but rather the presence of an oriented contour generating a congruent relation with those elements. Finally, the results of Experiment 5 extended the evidence provided by the previous experiments to top-heavy stimuli, which, albeit nonfacelike, share with faces the presence of more patterning in the upper part.

Together, these findings suggest that newborns' preference for faces does not depend exclusively, or entirely, on the facelike arrangement of the inner elements, which defines facedness. Rather, the results of the present study demonstrate that facedness is the emergent product of at least two different perceptual properties—top-heaviness and congruency—each of which is capable to elicit newborns' preferences when embedded in nonfacelike stimuli. In fact, the attentional biases for both these properties are thought to derive from basic constraints on the newborns' visual system (Acerra et al., 2002; Simion et al., 2002) that provide a comparable gain value for all visual patterns that possess certain structural/configural properties, irrespective of their resemblance to faces.

An aspect of the present findings, which merits discussion, relates to the lack of any significant result for the number of orienting responses variable. Although newborns looked significantly longer at the congruent nonfacelike stimulus in Experiment 1, at the congruent facelike stimuli in Experiments 3, 4, and 5, and at the congruent top-heavy stimulus in Experiment 5, they did not orient more frequently to these stimuli. This finding is not surprising, given that congruency is a configural property emerging from the spatial interrelations among the stimulus components that newborns may more easily appreciate when foveating the stimulus. Moreover, as proposed by other authors (e.g., Farroni, Menon, Rigato, & Johnson, 2007; Valenza et al., 1996), this finding may reflect the involvement of neural circuitry other than the subcortical visuomotor pathway that, according to the original version of the Johnson and Morton (1991) model of the development of face processing, would support the Conspec-like face detector responsible for newborns' face preference (Johnson, 2005).

Because stimuli in the periphery impinge on the temporal visual field that is known to feed predominantly into the subcortical visuomotor route, orienting responses are considered to likely reflect activity primarily within subcortical pathways (Simion, Valenza, Umiltà, & Dalla Barba, 1995, 1998).

To conclude, two final considerations should be raised concerning the interpretation of the data provided by the present study. First, we are aware that these data do not permit one to disentangle whether it is the same or rather two distinct factors that govern the preferences for facedness and the congruency property. In fact, the results of Experiments 2, 3, and 4 would be compatible with the interpretation that two distinct mechanisms may exist at birth, which work in parallel to drive newborns' attention. One of these would be a Conspec-like mechanism triggering newborns' attention toward stimuli displaying a facelike arrangement of the inner elements. The other mechanism could be nonspecific, responding to congruency and other general structural and configural properties of visual stimuli. According to this dual mechanism interpretation, the present results would show that the first mechanism is as powerful as the second in triggering newborns' attention and that the activation of the two mechanisms has an additive effect on newborns' preferences. However, because congruency is one of the configural/structural properties that characterize face stimuli, a more parsimonious explanation would be that newborns' visual behavior is governed by general rules that apply indifferently to faces and nonface stimuli. It has already been demonstrated that one of these rules concerns the up–down asymmetrical distribution of the features within the pattern (Simion et al., 2002). The present study provides evidence for a second rule concerning the spatial relation between the disposition of the inner features and the shape of the outer contour. Furthermore, examined more closely, the interpretation based on the existence of two separate mechanisms governing newborns' preferences for faces and nonface visual objects appears untenable. This is because, for Experiment 2, it would lead to predictions not confirmed by the actual results. Because the facelike stimulus used in Experiment 2 included both the facedness property and the general structural property of top-heaviness, this stimulus should have been preferred over the congruent nonfacelike stimulus in that it would activate both the face-specific and the general mechanisms. Instead, newborns' failure to manifest a preference for either stimulus renders more plausible the hypothesis of one single mechanism that would be sensitive to all the properties embedded in the stimulus, including top-heaviness and congruency, which together contribute to the overall facelike appearance of the stimulus.

A final aspect related to the interpretation of the present findings that should be acknowledged is the difficulty in unambiguously concluding that the attentional responses evoked by both the congruency and the top-heavy properties are of a nonspecific nature. Two different interpretations could be proposed as to why these two properties in combination trigger attention at birth. One possible interpretation is that the visual perceptual system has developed general attentional biases toward the congruency and top-heavy property, which in fact represent the nature's economical way of evolving a face detector. The alternative interpretation is that because facedness contains the congruency and top-heavy property as two of its defining characteristics, the innate face template matches better the nonface stimuli containing these two properties in comparison to other stimuli. Irrespective of the direction of this causal relationship, the demonstration provided by the present study of an additive effect of the two perceptual properties of congruency and top-heaviness on newborns' visual preferences appears crucial in the understanding of what makes a face to newborns.

Grownups Are Not Afraid of Scary Stuff, but Kids Are: Young Children's and Adults' Reasoning About Children's, Infants', and Adults' Fears

Liat Sayfan and Kristin Hansen Lagattuta
University of California, Davis

Three-, 5-, and 7-year-olds and adults ($N = 64$) listened to stories depicting 2 protagonists of different ages (infant and child or child and grownup) that encounter an entity that looks like a real (e.g., a snake) or an imaginary (e.g., a ghost) fear-inducing creature. Participants predicted and explained each protagonist's intensity of fear. Results showed significant age-related increases in knowledge that infants and adults would experience less intense fears than young children and that people's fears are causally linked to their cognitive mental states. Across age, stories involving imaginary beings elicited more frequent mental explanations for fear than stories about real creatures. Results are discussed in relation to children's developing awareness of the mind as mediating between situations and emotions.

Fear is one of the four basic emotions children experience, express, and identify in others from very early in life (Ekman, Sorenson, & Friesen, 1969). By using parent-report and child-report surveys, studies have found that 75%–95% of normal children experience an average of three to five specific fears of mild to moderate intensity (Gullone, 2000; Muris, Merckelbach, Gadet, & Moulaert, 2000). By the age of 3 years, most children exhibit fears of bodily injury, pain, natural phenomena (e.g., earthquakes), the dark, and animals (e.g., snakes). During the preschool years, children also begin to fear imaginary and supernatural creatures, including witches, monsters, and ghosts, with these fears of the imaginary and supernatural typically diminishing substantially by school age (Muris et al., 1997; Muris & Merckelbach, 2000).

Although we have ample information about the situations, objects, and creatures that young children fear, researchers have not systematically examined developmental changes in children's knowledge about the sources of fears as well as their awareness that people of different ages may experience different intensities of fear in the *same exact* situation. The current research addresses this missing piece by exploring 3- to 7-year-olds' knowledge about age differences in fears of real and imaginary creatures. In doing so, the current study provides a window into young children's awareness that people's emotions are not just elicited by objective situations but are also strongly shaped by the person's knowledge (e.g., knowledge about what is real vs. imaginary, knowledge vs. ignorance about an entity's capability to harm), characteristics (e.g., size and gender), and preferences (i.e., likes and dislikes).

Indeed, fear is an ideal context for examining children's early concepts about individual differences in emotions, especially how diversity in emotions may stem from differences in people's mental states. That is, fears are commonly elicited by thinking about the potential for harm, or in the case of fears of supernatural creatures, imagining something that does not exist. For this reason, fears commonly change with age and experience, as children increase their knowledge base as well as decrease their participation in fantasy play (Sarafino, 1986; Wenar, 1990). Moreover, it is likely that young children frequently encounter people with varying levels of fear in their everyday experiences, as when a mother chides, "You shouldn't be afraid—ghosts aren't real!" The current study examines whether 3- to 7-year-olds recognize that children typically experience more intense fears, especially fears of imaginary creatures, compared to adults (who know more) or young infants (who are naïve). Alternatively, young children may assume that fear depends just on the situation, rather than people's knowledge or attributes. If so, they may predict that all people will experience the same level of fear.

Prior research on children's emotion understanding reveals that most preschoolers have strong

knowledge about situational causes of emotions in that they can easily pair prototypic situations with common emotions (Harris, 1989). However, when a person's emotion cannot be easily explained by external events alone (e.g., feeling sad at a birthday party), young children often fail to consider the person's attributes, attitudes, or experiences (Denham, 1986; Gnepp, 1983; Gnepp & Gould, 1985). More recent research, however, reveals that young children have more than just a situational or script-like understanding of emotions (see Thompson & Lagattuta, 2006, for a review). Notably, even 4- to 6-year-olds can explain people's emotions as caused by their thoughts, memories, and anticipations (Lagattuta, 2007; Lagattuta & Wellman, 2001; Lagattuta, Wellman, & Flavell, 1997). Moreover, Rieffe, Meerum Terwogt, and Cowan (2005) report that 4-year-olds exhibit stronger awareness about mental causes of emotions in fear-inducing situations compared to happy-, anger-, or sad-arousing situations. Thus, although previous studies have been mixed, there is mounting evidence that young children know that both attributes of situations and people's minds determine emotions.

Finally, clues as to when young children may understand age-related differences in fear come from studies on children's knowledge that people of different age groups have different levels of factual knowledge (see Miller, 2000, for a review). That is, because fear is largely based on beliefs about potential harm from an object, entity, or situation (Oatley & Jenkins, 1996), different knowledge levels should translate into different fear experiences. Research has shown that although 4-year-olds appreciate that adults know more than children and children know more than babies, they have difficulty applying this awareness of knowledge diversity to make predictions about how people of different age groups would interpret partly occluded objects (Taylor, Cartwright, & Bowden, 1991). Further studies have shown that 4- to 8-year-olds exhibit the most difficulty assessing infants' knowledge and typically err on the side of overestimating what infants can know or do (Dowker, Hart, Heal, Phillips, & Wilson, 1994; Miller, Hardin, & Montgomery, 2003; Montgomery, 1993). More specific to the current research, in an unpublished dissertation, Phelps (1999) found that whereas 3-year-olds thought that adults are fearful of both real and imaginary entities, 4- and 5-year-olds asserted that adults are generally not afraid of most things. Nevertheless, all age groups maintained that babies would be afraid of monsters.

In summary, then, the current research examines developmental changes in young children's knowledge that people of different ages may have different fear reactions to identical situations. We presented 3- to 7-year-old children with vignettes featuring two people of different ages (a child and an infant or a child and a grownup) that encounter a stimulus that looks like a real (bee, spider, snake, and alligator) or an imaginary (witch, monster, ghost, and dragon) creature that preschool children commonly fear. We asked children to predict and explain the emotions of the story characters, including the intensity of each person's fear reaction (if afraid), using a 4-point pictorial intensity scale. Fear intensity was used because it enabled investigation into whether children believe the emotions of different age groups differ in *type* (afraid vs. unafraid) or whether they differ in degree of *intensity* (e.g., less afraid vs. more afraid).

Because prior research has been mixed as to whether young preschoolers understand individual or age-related differences in people's knowledge or emotions, for the last four story trials, we explicitly provided children with a direct comparison of the two people's contrasting emotional reactions (e.g., "[The child] is more afraid than the grownup right now") and asked them to provide an explanation. We reasoned that young children would provide more sophisticated person-oriented (particularly mention of cognitive mental states) explanations for emotions when they were explicitly prompted about divergent emotions (the *explain-different emotion* trials) versus when justifying their own emotion predictions.

Finally, because children's persistent fear of imaginary creatures has raised the question as to their ability to discern real entities from imaginary ones (Rosengren, Johnson, & Harris, 2000), at the end of the story-card procedures, we interviewed children about their own fears of the stimuli used in the vignettes as well as their understanding about the reality status of the imaginary creatures. College undergraduates were tested using the same procedures to measure adult reasoning and beliefs.

Method

Participants

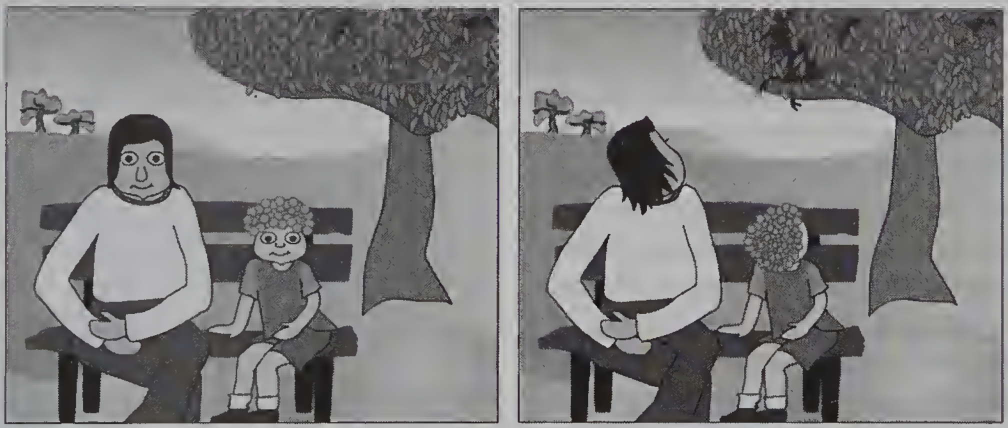
Sixty-four individuals in four age groups participated: sixteen 3-year-olds (age: $M = 3$ years 8 months, range = 3 years 4 months to 4 years 1 month), sixteen 5-year-olds ($M = 5$ years 4 months, range = 5 years 0 month to 5 years 10 months), sixteen 7-year-olds ($M = 7$ years 5 months, range = 7 years 0 month to 7 years 10 months), and sixteen young adults ($M = 20$ years 9 months, range = 18 years 8 months to 26 years

7 months), with equal numbers of males and females in each age group. Five additional 3-year-olds participated but never completed the interview due to inability or unwillingness to respond. The children were recruited from local schools and child-care centers in an ethnically diverse middle-class university town. Adults were recruited using the university introductory psychology subject pool. Of the adults, 50% were Caucasian, 25% Asian, 12.5% Hispanic, and 12.5% Other. Data were not collected on children's ethnicity, but they were predominantly Caucasian (approximately 75%).

Materials

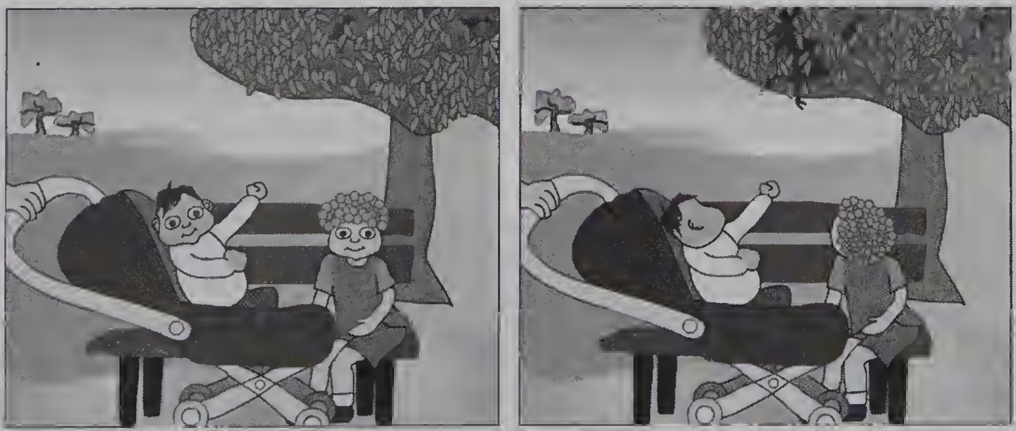
Participants listened to eight short stories accompanied by pictures illustrating each scene. Each story involved two protagonists: (a) a preschool boy or a preschool girl (the *child character*) and (b) either an androgynous grownup or an androgynous baby. In each story, the two protagonists engaged in a neutral behavior (e.g., sitting on the sand or standing near the stairs). Suddenly, they notice a potentially fear-inducing stimulus. The fear-inducing stimulus was described as either looking like a *real* ("It looks like a bee/a spider/an alligator/a snake") or an *imaginary* creature ("It looks like a ghost/a witch/a dragon/a monster"). The phrase *looks like* was included for both real and imaginary trials to make the wording linguistically parallel. Each stimulus was drawn so that it looked like a potentially scary thing, but it was unclear whether or not it actually was a scary thing (e.g., the snake could be interpreted as a worm or the ghost as a hanging piece of cloth). The wording of each story remained consistent across all stories with the exception of the story location, the characters involved, and the type of creature. Figure 1 shows the two versions of an imaginary creature story (the witch story). The child–grownup version is presented at the top of the figure and the child–baby version is presented at the bottom.

Each participant heard eight stories (about a spider, a snake, a bee, an alligator, a monster, a witch, a ghost,



Child-Grownup Version: "This is a story about a boy named Joe. One day Joe and his grownup friend are at the park. They sit together on a bench"

"Suddenly, they see something in the tree. It looks like a witch."



Child-Baby Version: "This is a story about a boy named Joe. One day Joe and his baby friend are at the park. They sit together on a bench"

"Suddenly, they see something in the tree. It looks like a witch."

Figure 1. Example of an imaginary creature story (the witch) with child–grownup pair (top) and child–baby pair (bottom).

and a dragon) in one of eight predetermined order sets. Each order set included two stories about a real entity with a child–grownup pair of protagonists, two stories about a real entity with a child–baby pair, two stories about an imaginary entity with a child–baby pair, and two stories about an imaginary entity with a child–grownup pair. Two of the real-entity stories had a girl as the child character (spider and snake stories) and two had a boy (bee and alligator stories). Similarly, two of the imaginary-entity stories were about a girl (monster and ghost stories) and two were about a boy (dragon and witch stories). To make sure that children interpreted these scenarios as events that could actually happen, the first story trial always involved a real creature. Additionally, because both the bee and the spider are similar stimuli, we included one in the first four story trials (Block 1) and one in the four last story trials (Block 2). In the same way, we separated the alligator and snake stories (both involve reptiles). The question order (whether participants predicted the child's vs. the grownup's or infant's reaction first) was counterbalanced across story trials.

Procedure

Each participant was interviewed individually in a quiet room in his or her school or in the laboratory. Before the interview began, the experimenter said, "You're going to hear a few short stories. I'm going to ask you questions about the people in the stories. There is no 'right' or 'wrong' answer; whatever you tell me is fine. I just want to know what you think." They were then pretrained on how to interpret and use the 4-point fear intensity scale (see Figure 2 for the scale illustration). Participants then heard eight short stories involving a potentially fear-inducing stimulus. Following each story, the experimenter asked the participant to predict each of the character's emotions (e.g., "Do you think the baby is afraid or not afraid right now?"), to specify the intensity of each of their fears (if predicted) using the 4-point scale (e.g., "How afraid is the baby?"), and to explain the cause of each of their emotions (e.g., "Why is the baby [not] afraid right now?"). To help participants clarify and expand their explanations, the experimenter paraphrased their responses and encouraged them to provide additional information. If children answered "I don't know," they were reminded that there were no right or wrong answers and encouraged to take a guess. When it was clear that the participant had no further explanations (after being asked three times), the experimenter proceeded to the next trial.

During the last four story trials, after participants provided their own emotion predictions and explanations, the experimenter explicitly told and showed them that the two characters were experiencing different levels of fear and she asked them to explain the reason for this difference (the explain-different emotion trials). Specifically, participants were asked: "Why do you think the baby/grownup is less/more afraid than [Joe] right now?" (the use of the terms *more* vs. *less* was counterbalanced across trials). Because prior research has shown that 3-year-olds may better comprehend the meaning of the linguistic term *more* versus *less* (even though they know that both are comparative terms; Palermo, 1974; Wannemacher & Ryan, 1978), this question was always accompanied by a story card that clearly juxtaposed the different intensities of fear experienced by the two protagonists. If children showed any confusion about how to interpret the question, it was rephrased with the other comparative term (e.g., "Why is Joe more afraid than the baby" instead of "Why is the baby less afraid than Joe?"). Figure 3 shows the picture cards used for the explain-different emotion trials for the child–grownup (top) and child–baby (bottom) versions of the witch story.

After participants responded to the eight story trials, the experimenter asked them whether or not they, themselves, feared the creatures presented in the stories (e.g., "Are you afraid or not afraid of spiders?"). If they said that they were afraid, the experimenter asked them to indicate the intensity of this

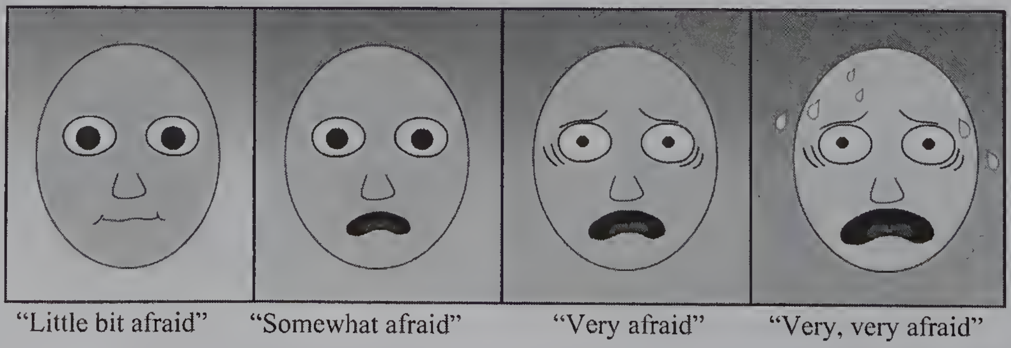


Figure 2. The fear intensity scale.

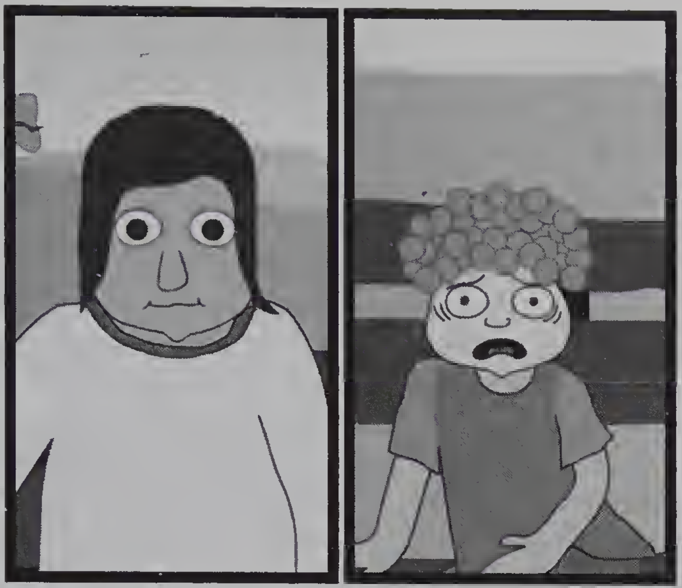
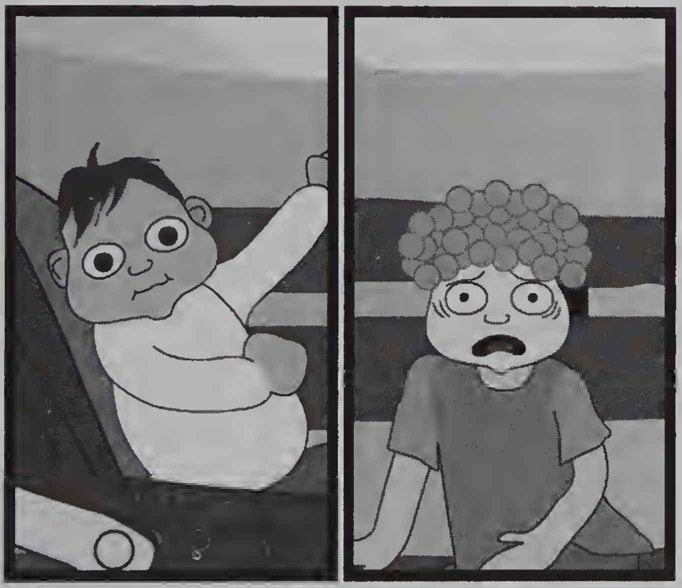


Child-Grownup Version: "Now, let's see how Joe and his friend are really feeling. Look! The grownup is less afraid than Joe."



Child-Baby Version: "Now, let's see how Joe and his friend are really feeling. Look! Joe is more afraid than the baby."

Figure 3. Examples of the explain-different emotion ending for the witch story with child–grownup pair (top) and child–baby pair (bottom).

fear on the pictorial scale (i.e., "Show me how afraid you are"). Finally, children were asked to judge whether each stimulus really existed (e.g., "Are there any real witches in the world?"). To verify that the reality question was interpreted correctly for the imaginary creatures, whenever participants validated the existence of an imaginary creature, the experimenter asked them to explain how they view the entity (e.g., "When you say witches are real, what do you think a witch is?"). This enabled us to count only endorsements that fit supernatural criteria. For example, if a participant said, "Yes, there are real dragons," but then went on to mention the large reptiles known as komodo dragons, this would not be counted as an endorsement of imaginary dragons (for witches, they had to mention something about being able to do magic or cast spells; for ghosts, it had to be an incarnation of a dead person; and for monsters, it could not simply be a real animal with a deformity).

Each session was tape-recorded and transcribed verbatim. After completion of the session, child participants received a small reward and adult participants were given course credit for their participation.

Coding of Fear Explanations

Participants' explanations for the story characters' fear reactions were coded into two main categories: *stimulus oriented* and *person oriented* (see Table 1 for examples). Stimulus-oriented explanations focused on the features of the creature itself, including its identity, size, and capability to harm. In contrast, person-oriented explanations explained emotions in relation to features or qualities of the story character. There were three subtypes of person-oriented explanations. *Attribute explanations* included mention of the protagonist's external characteristics (e.g., size), gender, or age. *Preference explanations* attributed the cause of emotions to the protagonist's desires, likes, or dislikes and included verbs such as like, love, hate, dislike, or want. Finally, *mind explanations* focused on the protagonist's cognitive mental states and included mental verbs such as *know, believe, think*, or *realize*. Because participants often provided multiple emotion explanations for a single character, their complete explanation could be coded into one or into multiple categories. For example, the explanation, "[He's afraid because] the alligator might come closer. He doesn't want the grownup to smash it down. The alligator might splash water on him" would be coded as both stimulus oriented and person oriented (preference). This is because the child explained fear in relation to the alligator potentially coming closer and splashing water (stimulus oriented) as well as in relation to what the character does not want to happen (person oriented, preference).

The principal investigator and two undergraduate research assistants collaboratively coded 25% of the transcripts. After this training session, the research assistants, who were blinded to the study hypotheses and to what were considered more sophisticated explanations, independently coded the remaining 75% of the transcripts into the different categories of explanations using explicit criteria. All disagreements were resolved by discussion. Kappa coefficients for the different explanation categories, including all subcategories, were high, ranging between .91 and .96.

Table 1

Examples of Children's Explanations for Why Characters Are Afraid or Not Afraid by Age Group and Explanation Type

	Age group			
Explanation type	3-year-olds	5-year-olds	7-year-olds	Adults
Stimulus oriented	Because *the snake is nice.*	The *witch is gonna take him* away and never come back.	*It's* just might be *a bug*.	*Witches don't attack* in daylight.
	Because *it's not getting out* of the water.		It's just a *grizzly bear.*	*Alligators can kill* you.
Person oriented: Mind	*She thinks* ghosts are scary.	He's scared because *he thinks* the dragon will see him and blow fire at him and he's gonna burn up.[a]	He's at the age when *he believes* in those things.	The baby *doesn't know* what is going on.
	Because *she thought* it's a monster.		*He thinks* it is just a shadow.	*Pete knows* its just a fish.[a]
			He thinks the witch is gonna get him and put him in stew.[a]	She *doesn't know* that spiders don't hurt people.[a]
Person oriented: Preferences	The baby's afraid because it *doesn't like* spiders.	*He doesn't want* the alligator to eat him.[a]	The grownup *likes* snakes.	*He doesn't want* to be around this thing.
	She *doesn't want* to have a dragon there.		*He doesn't want* the witch to hurt him.[a]	
Person oriented: Attributes	Because *he's just a tiny, tiny baby.*	Grownups aren't afraid. *They're bigger* than little kids.	*She can't run* as fast.	Because *little girls* get scared of spiders.
			Babies get scared when they see stuff that's big.[a]	*She's* only *a child.*

Note. Coders made decisions about the explanations' classifications based on the italicized key phrases.

[a] These explanations were also coded as stimulus oriented because they describe features or capabilities of the entity as well.

Results

Several approaches were taken to investigate developmental changes in children's knowledge that people of different age groups would experience different emotions in the same situation. First, we focus on the number of trials that children and adults predicted that the emotions of the two story characters would differ by *type* (one is afraid and the other is not afraid). Next, we examine the number of trials that children and adults predicted that the characters' fear reactions would differ in *intensity* (one is more or less afraid than the other). Final prediction analyses examine whether predictions about the intensity of characters' fear reactions varied by the age of the character (baby vs. child vs. grownup) or the reality status of the stimulus (real vs. imaginary). Prediction analyses are then supplemented by an examination of children's and adults' *explanations* for the causes of characters' emotions.

Because preliminary analyses revealed no significant main effects or interactions for story order or gender of child story character, these factors were not considered further (see individual sections subsequently for how data were scored). Participant gender was also removed from the primary analyses because it had no significant main effects or interactions on predictions or explanations aside from one exception. There was a significant main effect for participant gender for fear intensity predictions, $F(1, 56) = 5.78$, $p < .05$, with males ($M = 1.34$, $SE = 0.10$) attributing more intense fear to story characters than females ($M = 1.01$, $SE = 0.11$). Finally, 3-year-olds did not show greater confusion when the explain-different-emotion question was phrased as "less" versus "more" afraid. They answered "I don't know" as their first response for 22% of the trials, regardless of comparative term.

Except when otherwise noted, data were analyzed using repeated measures analysis of variance (ANOVA). Alpha was set at .05, and thus, all results reported as significant are $p < .5$ or better. Significant main effects were followed up with Tukey's honestly significant difference (HSD) tests to evaluate pairwise comparisons, with only significant pairwise comparisons among means reported. Simple effects tests were used to examine significant interactions. Partial eta squares, computed using SPSS, are provided as a measure of effect size for all significant main effects and interactions.

Analyses of Fear Predictions

Predicting fear versus nonfear reactions. First, we examined the frequency that children and adults predicted that two characters' emotions in the same situation would vary by type (dichotomously): afraid versus not afraid. Participants were given a score of 1 for every trial that they predicted that the pair of characters (child – baby or child – grownup) would have different reactions (one character is afraid and the other is not afraid). A score of 0 was given when participants predicted both characters would have the same reaction (i.e., both "afraid" or both "not afraid"). All scores were averaged across trials.

A 4 (age: 3-year-olds, 5-year-olds, 7-year-olds, and adults) × 2 (entity type: real vs. imaginary) × 2 (pair: child – baby vs. child – grownup) repeated measures ANOVA for predict-different-emotion scores resulted in a main effect for entity type, $F(1, 60) = 6.53$, $\eta_p^2 = .10$, with all age groups predicting dissimilar fear reactions significantly more often in situations that involved imaginary entities ($M = 0.54$, $SE = 0.04$) than in situations involving real entities ($M = 0.45$, $SE = 0.04$). Separate post hoc t tests, however, showed that all participants, even the adults, were at chance level (50%) when attributing differential fear versus nonfear reactions to characters, $ts(15) < 1.27$, $ps > .22$.

Predicting differential intensity of fear. Next, we examined whether children and adults predicted that two people in the same situation would vary in the *intensity* of their fear reactions (more vs. less afraid). Participants received a score of 1 for every trial that they predicted that each character in the pair (child – baby or child – grownup) would experience a different level of fear (one character is *more* afraid than the other or one character is afraid and the other is not). A score of 0 was given when participants predicted both characters would have the same *intensity* of fear reaction. Again, these scores were averaged across trials.

A 4 (age: 3-year-olds, 5-year-olds, 7-year-olds, and adults) × 2 (entity type: real vs. imaginary) × 2 (pair: child – baby vs. child – grownup) repeated measures ANOVA yielded main effects for age, $F(1, 60) = 3.5$, $\eta_p^2 = .15$, and for entity type, $F(1, 60) = 5.2$, $\eta_p^2 = .08$. The frequency that participants predicted that the two characters' fear reactions would differ in intensity significantly increased with age (3-year-olds: $M = 0.50$, 5-year-olds: $M = 0.63$, 7-year-olds: $M = 0.70$, and adults: $M = 0.80$, and all SEs $= 0.05$). Post hoc Tukey's HSD comparisons showed that 3-year-olds predicted different fear intensities for characters significantly less often than 7-year-olds or adults and that 5-year-olds also made such predictions significantly less often than adults. Additionally, participants of all age group predicted dissimilar fear reactions significantly more often for stories about imaginary entities ($M = 0.70$, $SE = 0.04$) versus real entities ($M = 0.61$,

$SE = 0.04$). Separate t tests showed that 3-year-olds predicted different emotions at above chance levels for the stories about imaginary entities, $ts(15) > 3.1$; however, they were at chance when predicting different emotions for characters encountering real entities, $ts(15) < 2.09$. All other age groups predicted different emotions at greater than chance levels across all entity types, $ts(15) > 2.6$.

Fear intensity attributed to characters across story trials. Next, we explored developmental trends in predicting different intensities of fear (ranging from 0 = *no fear* to 4 = *intense fear*) for people in relation to their age (infants, children, and grownups) and the reality status of the stimuli (real vs. imaginary). Because the child character appeared in every trial, child character scores were averaged across the four trials for each entity type (real or imaginary). Scores for companion characters (baby and grownup) were averaged across the two trials for each entity type that each character appeared. Table 2 and Figure 4 display the primary results. A 4 (age: 3-, 5-, and 7-year-olds and adults) × 3 (character: infant, child, and grownup) × 2 (entity type: real vs. imaginary) repeated measures ANOVA for fear intensity predictions revealed main effects for character, $F(2, 120) = 24.39$, $\eta_p^2 = .29$, and for entity type, $F(1, 60) = 14.88$, $\eta_p^2 = .20$, a significant Character × Entity Type interaction, $F(2, 120) = 7.39$, $\eta_p^2 = .11$, and a significant Age Group × Character interaction, $F(6, 120) = 7.49$, $\eta_p^2 = .27$; all qualified by a three-way interaction between age group, character, and entity type, $F(6, 120) = 3.02$, $\eta_p^2 = .13$.

To clarify the three-way interaction, we performed separate 3 (character: infant, child, and grownup) × 2 (entity type: real vs. imaginary creatures) repeated measures ANOVAs for each age group. For the 3- and 5-year-old group, this resulted only in a main effect for character, $F(2, 30) = 8.12$, $\eta_p^2 = .35$, and $F(2, 30) = 10.85$, $\eta_p^2 = .42$, respectively. For the 7-year-olds and the adults, there was a significant Character × Entity Type interaction, $F(2, 30) = 9.50$, $\eta_p^2 = .39$, and $F(2, 30) = 7.33$, $\eta_p^2 = .33$, respectively, qualifying a main effect for entity type for the 7-year-olds, $F(1, 15) = 9.83$, $\eta_p^2 = .40$, and a main effect for character for the adults, $F(1, 15) = 32.51$, $\eta_p^2 = .68$.

Table 2

Participants' Predictions of Fear Intensity by Age Group and Story Character

	Story character		
Age group	Infant	Child	Grownup
3-year-olds	1.58 (1.30)	1.02 (1.05)	0.45 (0.74)
5-year-olds	2.19 (1.60)	1.43 (1.00)	0.73 (0.94)
7-year-olds	1.29 (1.04)	1.27 (0.87)	0.83 (0.77)
Adults	0.88 (0.97)	2.12 (0.71)	0.89 (0.92)

Note. The fear scale ranged from 1 (*little bit afraid*) to 4 (*very very afraid*). The means presented here also include the prediction of *not afraid* coded as 0. The same pattern of results emerged when we excluded "not afraid" predictions and considered only fear predictions. Standard deviations are presented in parentheses.

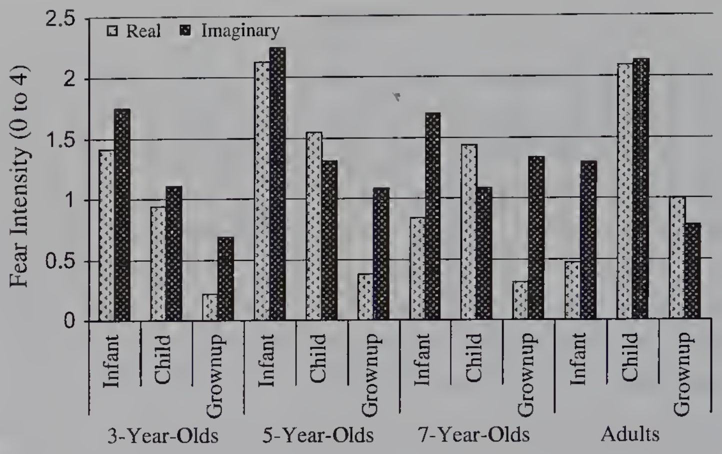


Figure 4. Participants' fear predictions by age group, story character, and entity type.

As shown in Table 2, 3- and 5-year-olds attributed more intense fears to the infant characters followed by the child characters and the least intense fears to the grownup characters. Similarly, 7-year-olds attributed the least intense fears to the grownup characters; however, they predicted equivalent fear intensities for the child and infant characters. Finally, adults judged that child characters would experience the most intense fears and infants and grownups would experience the least intense fears.

Figure 4 shows data on participants' fear predictions by entity type. As shown in Figure 4, within the stories about *real* creatures, both 7-year-olds and adults predicted the most intense fears for children ($M = 1.44$, $SE = 0.24$ and $M = 2.10$, $SE = 0.24$, respectively), followed by both infants ($M = 0.84$, $SE = 0.29$ and $M = 0.47$, $SE = 0.29$, respectively) and grownups ($M = 0.31$, $SE = 0.17$ and $M = 1.00$, $SE = 0.17$, respectively). Within the stories about *imaginary* creatures, 7-year-olds predicted that children would be less afraid ($M = 1.09$, $SE = 0.22$) than both grownups ($M = 1.34$, $SE = 0.22$) and infants ($M = 1.70$, $SE = 0.33$). However, adults predicted that children would be the most afraid ($M = 2.14$, $SE = 0.22$) compared to both grownups ($M = 0.78$, $SE = 0.22$) and infants ($M = 1.30$, $SE = 0.33$). Finally, simple effects tests revealed that 7-year-olds predicted that both infants and grownups would be more afraid of imaginary things ($M = 1.70$, $SE = 0.33$ and $M = 1.34$, $SE = 0.22$, respectively) than real things ($M = 0.84$, $SE = 0.29$ and $M = 0.31$, $SE = 0.17$, respectively) and that children will be equally afraid of both real

($M = 1.44$, $SE = 0.24$) and imaginary ($M = 1.09$, $SE = 0.22$). On the other hand, adults predicted that infants would be more afraid of imaginary things ($M = 1.30$, $SE = 0.33$) than real things ($M = 0.47$, $SE = 0.29$), whereas children and grownups would be equally afraid of both real ($M = 2.10$, $SE = 0.24$ and $M = 1.00$, $SE = 0.17$, respectively) and imaginary creatures ($M = 2.14$, $SE = 0.22$ and $M = 0.78$, $SE = 0.22$, respectively).

Emotion Explanations

As described in the Method section, participants' emotion explanations were coded into several categories (Table 1). Participants were given a score of 1 for every trial that they provided a particular type of explanation for each character's emotion (i.e., person oriented or stimulus oriented, including the different subtypes of person-oriented explanations). Explanation scores were averaged across the number of trials in which each character appeared for each entity type (i.e., across the four imaginary and four real trials for child characters and across the two imaginary and two real trials for grownup and infant characters). Additionally, we averaged the number of trials participants offered both types of explanations at the same time (i.e., a combined stimulus- and person-oriented explanation).

Table 3 displays these data, converted to percentage of trials for ease of interpretation. A 4 (age group: 3-, 5-, and 7-year-olds and adults) × 3 (explanation type: stimulus oriented, person oriented, and both) repeated measures ANOVA revealed main effects for explanation type, $F(2, 120) = 11.71$, $\eta_p^2 = .16$, and age group, $F(3, 60) = 4.27$, $\eta_p^2 = .18$, and a significant Age Group × Explanation Type interaction, $F(6, 120) = 4.40$, $\eta_p^2 = .18$. As shown in Table 3, exclusive stimulus-oriented explanations significantly decreased with age as combined explanations referring to both the stimulus and the person significantly increased. There were no differences between the age groups for the frequency of exclusive person-oriented explanations.

To further elucidate the developmental progression of children's emotion explanations, we examined age-related changes in the provision of the three subcategories of person-oriented explanations. Three separate repeated measures ANOVAs on mind explanations, preference explanations, and attribute explanations were conducted, with age group as the between-subject factor and character and entity type as the within-subjects factors. Table 4 shows these data. For the mind explanations, we found main effects for age group, $F(3, 60) = 18.99$, $\eta_p^2 = .49$, and for entity type, $F(1, 60) = 20.86$, $\eta_p^2 = .26$. Specifically, 5- and 7-year-olds and adults provided mind explanations significantly more often than 3-year-olds. Additionally, all age groups explained emotions in relation to characters' cognitive mental states significantly more often in situations involving imaginary versus real things. For the preference explanations, there was only a main effect for age group, $F(3, 60) =$

Table 3
Stimulus- and Person-Oriented Explanations by Age Group and Entity Type[a]

	Age group			
Entity type	3-year-olds	5-year-olds	7-year-olds	Adults
Exclusive stimulus-oriented explanations				
Real[b]	43	27	31	25

Imaginary[b]	23	55	47	64
Total[c]	21	48	40	60

[a] All numbers are percentages of trials. Note that percentages for each group do not add up to 100% because some explanations did not fit any of the categories.
[b] Percentages of trials out of 64 per age group.
[c] Percentages of trials out of 128 per age group.

Table 4
Character's Mind, Attributes, and Preferences Explanations by Age Group and Entity Type[a]

	Age group			
Entity type	3-year-olds	5-year-olds	7-year-olds	Adults
Character's mind				
Real[b]	4	35	29	56
Imaginary[b]	8	50	50	70
Total[c]	6	43	39	63
Character's preferences				
Real[b]	24	7	5	4
Imaginary[b]	21	3	1	2
Total[c]	22	5	3	3
Character's attributes				
Real[b]	22	33	31	27
Imaginary[b]	23	21	24	35
Total[c]	23	27	27	30

[a] All numbers are percentages of trials. Note that percentages for each group do not add up to 100% because some explanations did not fit any of the categories.
[b] Percentages of trials out of 64 per age group.
[c] Percentages of trials out of 128 per age group.

4.61, $p < .01$, $\eta_p^2 = .19$, with 3-year-olds providing significantly more preference explanations compared to 5- and 7-year-olds and adults, respectively. Findings for attribute explanations were null.

Explaining own predictions versus explaining different emotions. Recall that during the last four story trials, after participants offered their own judgments about story characters' likely emotions, the experimenter explicitly told and showed them that the two characters had fear reactions that differed in intensity (e.g., "Look! The baby is less afraid than Sue"; Figure 3). We compared participants' emotion explanations for these prompted trials to their responses when they explained emotions that they had predicted for story characters. Three separate repeated measures ANOVAs were performed: the first on the number of trials stimulus-oriented explanations were offered exclusively, the second on the number of trials both stimulus- and person-oriented explanations were offered together, and the third on the specific subcategory of person mind explanations. For all analyses, character (3: child, grownup, and baby) and question type (2: explain-own prediction vs. explain-different emotions) were the within-subjects variables and age group (4: 3-, 5-, and 7-year-olds and adults) was the between-groups variable.

All three analyses yielded main effects for question type, $F(1, 51) = 26.19$, $\eta_p^2 = .32$; $F(1, 55) = 17.01$, $\eta_p^2 = .26$; and $F(1, 55) = 8.4$, $\eta_p^2 = .13$, respectively. Participants of all age groups gave exclusive stimulus-oriented explanations significantly less often (16% vs. 30% of trials) and combined stimulus- and person-oriented explanations significantly more often (78% vs. 66% of trials) for trials where they were directly asked to explain why two characters had different emotions. Moreover, participants of all ages explained emotions in relation to characters' cognitive mental states significantly more often in explain-different emotion versus explain-own prediction trials (48% vs. 38% trials). Main effects for age group also emerged in these analyses (as discussed earlier).

Other Findings

At the end of the interview, we asked participants to self-report their own fears of the real and imaginary stimuli used in the stories. Comparing children's own fear reactions to those they attributed to the child characters in the stories, we found that 3-year-olds predicted more intense fears for the child protagonists than for themselves ($M = 1.00$, $SE = 0.08$ vs. $M = 0.15$, $SE = 0.21$), $F(1, 15) = 15.81$, $\eta_p^2 = .51$. In contrast, 5-year-olds and adults attributed the same level of fear to themselves ($M = 1.15$, $SE = 0.22$ and $M = 0.96$, $SE = 0.14$, respectively) as to the same-aged protagonists (i.e., child or grownup; $M = 1.33$, $SE = 0.23$ and $M = 0.89$, $SE = 0.19$, respectively); $Fs < 3.01$. Seven-year-olds provided matched self-other predictions in scenarios featuring real creatures; however, they predicted significantly less intense fears of imaginary creatures for themselves ($M = 0.29$, $SE = 0.19$) than for the child protagonists ($M = 1.09$, $SE = 0.23$), $F(3, 60) = 3.37$, $\eta_p^2 = .14$.

Finally, we questioned participants about their belief regarding the reality–fantasy distinction. As shown in Table 5, almost two thirds of the 3-year-olds insisted that at least one of the four imaginary creatures exist, with ghosts, witches, and monsters (in descending order) being the most commonly endorsed creatures ($M = 2.2$ out of the four imaginary creatures were endorsed as real by 3-year-olds; range = 0–4). On the other hand, only one 5-year-old claimed that these creatures exist (a ghost). Judgments that one or more of the imaginary creatures is or could be real (*could be* = the participant answered "maybe" to the "yes–no" question about whether the creature existed) increased at age 7 ($M = 44\%$) and continued to rise to adulthood ($M = 63\%$). Seven-year-olds and adults most frequently endorsed the real or potential existence of ghosts and then witches ($M = 1.29$ imaginary creatures endorsed by 7-year-olds, range = 0–2; $M = 1.5$ for adults, range = 0–2). Chi-square analyses confirmed significant age differences in beliefs that imaginary creatures "maybe" or "do" exist, $\chi^2(3) = 13.71$, $p < .01$, with a significant decline between 3 and 5 years and a significant increase between 5 and 7 years. Note that these data do not include interpretations of witches as humans who merely identify themselves as witches, dragons

Table 5

Percentage of Participants Endorsing the Possible Existence of Imaginary Creatures

	Age group			
Does it exist?	3-year-olds	5-year-olds	7-year-olds	Adults
"Yes"[a]	63	6	19	31
"Maybe"[a]	0	0	25	38
Either "yes" or "maybe"[a]	63	6	44	63
"No" to all[b]	37	94	56	37

[a] All numbers are percentages of participants who endorsed the existence or possible existence of at least one of the four imaginary creatures (ghosts, witches, monsters, and/or dragons).

[b] All numbers are percentages of participants who said that all four imaginary creatures do not exist.

as komodo dragons, monsters as deformed real animals, or ghosts as people dressed up.

Discussion

Results of the current study reveal that between the ages of 3 and 7 years, children develop increasing awareness that infants, children, and adults can have different emotional reactions to the same potentially fear-inducing situations. Developmental changes in fear predictions were accompanied by age-related increases in attention to character's *minds* (i.e., beliefs and knowledge) as the cause of person's fear or lack of fear, as opposed to the stimulus itself. Such mental explanations were particularly prevalent when explaining characters' fears of imaginary versus real creatures. These data advance current knowledge about the development of children's understanding of mind and emotion during early childhood.

Predictions of Fear

Children and adults predicted whether infant, child, and adult protagonists in the same situation would feel afraid versus not afraid and then made judgments about the intensity of characters' fears (if afraid). Results showed that young children as well as adults predicted that one character would feel afraid and the other character would experience no fear only 50% of the time (chance level). Significant age differences emerged, however, in participants' predictions of fear intensity. Between the ages of 3 and 7 years, children increasingly predicted different levels of fear for different-aged characters, with 5- and 7-year-olds and adults predicting different fear intensities for different characters significantly above chance for all story types (3-year-olds were above chance just for imaginary creature trials). Thus, 5- and 7-year-olds as well as adults, most frequently judged that people of different ages in the same potentially fear-inducing situation would experience emotions that differed not in absolute type (one afraid and the other not afraid) but rather in the relative *degree* of fear.

Significant age differences also appeared in the specific fear intensity predictions children and adults provided: both in relation to the character experiencing the emotion and in relation to whether the entity was real versus imaginary. First, participants of all age groups, even 3-year-olds, judged that child-aged protagonists would be significantly more afraid than grownups in situations involving a potential threat from a real creature. Importantly, however, 3- and 5-year-olds thought babies would be significantly more afraid than children, 7-year-olds thought babies and children would experience the same level of fear, and adults predicted that both babies and adults would experience less fear than child-aged protagonists. These data confirm and extend previous studies showing that 3- to 8-year-olds typically overestimate, or are simply confused about, what babies know and can do (Dowker et al.,1994; Miller et al., 2003; Montgomery, 1993; Taylor et al., 1991). In many respects, young children's confusion about the emotions of infants is not surprising. That is, children have much more limited exposure to babies in comparison to adults and same-aged peers, and they may hear contrasting opinions about infant abilities from people around them. Indeed, even adults from different cultural and social classes have divergent ideas about infants' cognitive and emotional capacities (Reznick, 1999; Reznick & Schwartz, 2001).

Finally, significant developmental changes were also apparent in participants' judgments about whether the type of potentially fearsome entity would cause different fear reactions. Whereas 3- and 5-year-olds did not differentiate fear predictions by the reality status of the entity, 7-year-olds and adults predicted that people's fears of imaginary creatures would be more intense. Still, aside from the 7-year-old group, all age groups' judgments about the relative intensity rankings of different age groups' fears were equivalent across scenarios featuring real or imaginary creatures. That is, 3- and 5-year-olds expected babies to be most afraid and adults to be least afraid in all situations, and adults expected child-aged protagonists to be more afraid than babies or adults of both real and imaginary creatures. Curiously, although 7-year-olds predicted that infants and adults would show *less* fear than child protagonists in situations featuring real creatures (same as adults), they predicted that infants and adults would experience *more* intense fear than child protagonists in scenarios featuring potential threats from imaginary creatures (opposite to the adult pattern). We will reserve interpreting this peculiar finding for the 7-year-olds until discussing results for children's predictions about their own fears of the real and the imaginary.

Explaining the Causes of Fear

Participants' explanations for emotions provide a deeper look into the development of children's knowledge about the causes of fear. Between the ages of 3 and 7 years, children offered significantly fewer explanations that pertained just to characteristics or capabilities of the stimulus (e.g., "The bee can sting him" and "The dragon can blow fire at them") and significantly more explanations that considered both the person (characteristics, preferences, and capabilities) and the stimulus simultaneously (e.g., "He *knows* that if he stands still the bee won't sting him"). Even within these combined person + stimulus explanations, there were important age differences. Whereas 3- and 5-year-olds typically focused on people's physical attributes (e.g., "Because the baby is tiny") or preferences (e.g., "Because she doesn't like snakes"), 7-year-olds and adults more often focused on character's cognitive mental states (e.g., "The baby is too young to *realize* what this thing is"). Thus, with increasing age, children evidenced greater knowledge that it is not the stimulus per se that induces fear but that fear reactions are mediated by the person's mind, especially his or her thoughts, beliefs, and knowledge. This finding challenges previous conclusions that preschoolers are mere "situationists" in that they base emotion predictions on objective features of the situation alone (e.g., Gnepp, 1989; Gnepp, Klayman, & Trabasso, 1982) and confirm more recent data suggesting that even young children are cognizant of mental causes of emotions (e.g., Lagattuta, 2007; Lagattuta & Wellman, 2001; Lagattuta et al., 1997; Pons, Harris, & de Rosnay, 2004; Rieffe et al., 2005).

Interestingly, all age groups, including 3-year-olds, referred significantly more often to the characters' cognitive mental states when explaining emotions in scenarios involving potential threats from imaginary versus real creatures. This earlier precocity in reasoning about mind – fear connections in the context of imaginary threats fits well with previous research showing that preschoolers' heightened fears often result from thinking about or imagining scary things (Muris et al., 1997, 2000). Indeed, during this age period, children spend a considerable amount of time pretending, play that often involves supernatural beings (Woolley, 1997). Children's direct experience of becoming afraid after thinking about or imagining supernatural creatures may contribute to their earlier recognition of the influence of the mind on fears of dragons, witches, ghosts, and monsters. Children's enhanced knowledge may also stem from direct adult instruction. That is, in their attempts to calm their children's fears, parents likely explain that even though people can imagine things like monsters in their minds, these creatures are not real. These assumptions regarding connections between parent – child discourse and children's knowledge about mental causes of fear need to be explored in future research before stronger conclusions can be made.

Still, it is important to consider that it may not be the inclusion of supernatural beings per se that provoked children and adults to provide significantly more mental explanations for emotions in the imaginary versus real creature scenarios. Even though both real and imaginary stimuli were drawn ambiguously (the snake could be a worm and the ghost could be a light) and the phrase *looks like* (a snake, a ghost, etc.) was included across all trial types, scenarios involving imaginary creatures were, by their very nature, more *uncertain* situations. That is, if something looks like a snake, it could really be a snake, but if it looks like a dragon, but dragons do not exist, then the identity of the creature (and one's emotional reaction to it) is more dependent upon a person's knowledge, beliefs, and expectations. Recall that Rieffe et al. (2005) found that 4-year-olds frequently provided mental explanations for a character's fear: The scenario they used involved the uncertain situation of a person entering a dark room occupied by an unknown person. Thus, future research is needed to examine whether supernatural status or just general uncertainty about the identity of a potentially dangerous entity elicits more frequent mental explanations for fear from children and adults.

Finally, results from explanation analyses showed that asking children to explain differences in people's reactions ("Look! The baby is less afraid than the child!") enabled young children to demonstrate stronger knowledge that people's minds can mediate between situations and emotions. These explain-different emotion trials provoked significantly more cognitive mental state explanations for emotions (e.g., "The grown-up knows that ghosts are not real") than the *predict-and-explain* trials. These data converge with recent findings that asking young children to explain divergent or unexpected behaviors or emotions can be an effective tool for uncovering more sophisticated reasoning about people's minds in young children (Bartsch & Wellman, 1995; Lagattuta 2005; Robinson & Mitchell, 1995; Tardif, Wellman, & Cheung, 2004). Still, it is important to acknowledge that even with the inclusion of an explicit prompt to explain divergent emotions, the majority of 3-year-olds' emotion explanations were stimulus- rather than person oriented. Thus, 3-year-olds' understanding about mind – emotion connections is clearly more fragile and less coherent than that of older children and adults.

Self Versus Others and Ontological Reasoning

When asked to rate the intensity of their own fears of the creatures included in the story scenarios (at the end of the interview), 5-year-olds and adults matched their personal fear ratings with those they predicted for the same-aged characters in the scenarios. In contrast, 3-year-olds predicted significantly higher fears for child-aged protagonists than for themselves, and 7-year-old predicted significantly more intense fears of imaginary (but not real) creatures for child-aged protagonists than for themselves. If children make sense of others' emotions by considering how they would feel in that situation (Harris, 1989), then why did 3- and 7-year-olds make different emotion reports for themselves than for same-aged story characters?

Previous research has shown that preschool-aged children often evaluate themselves in a highly positive and ideal manner (Harter, 1999) and strive to increase their ability to act autonomously or be a "big kid" (see Lagattuta & Thompson, 2007, for a review). Because fear can be regarded as a sign of weakness or babyishness, 3-year-olds may have exaggerated their own personal courageousness while at the same time acknowledged that children of their same age do experience fear. Alternatively, when asked about their own fears, 3-year-olds might simply not be aware that they indeed are afraid of these creatures.

Divergence in self versus other emotions predictions for 7-year-olds may result from different developmental processes. Starting around the ages of 7 – 9 years, children begin to engage in more hypothetical or counterfactual thinking as well as show stronger knowledge that people can have different interpretations about what is real (Siegler & Alibali, 2005). These cognitive advances may lead children to begin questioning their assumptions that supernatural creatures do not exist. Indeed, as shown in our data, there was a significant increase between 5 years (6% participants) and 7 years (44% participants) in judging that one or more of the imaginary creatures (especially ghosts) are or could be real. This remained high even for adult participants (63% participants; see also Rice, 2003, for evidence that many adults endorse the existence of supernatural creatures). These data fit with recent findings from Harris, Pasquini, Duke, Asscher, and Pons (2006) that between 4 and 8 years of age, children become increasingly aware that people hold mixed opinions about whether "equivocal beings" such as ghosts, monsters, and angels exist in real life.

Because 7-year-olds are transitioning into a period of questioning the possibility of the supernatural, this may have caused their reasoning on the imaginary creature trials to be nuanced and inconsistent compared to the other age groups' responses. Seven-year-olds predicted higher levels of fear of imaginary creatures for child-aged protagonists than for themselves (but made corresponding self-other predictions for real creatures), and they predicted that adults and babies would be more afraid than children when encountering something that looks like a ghost, witch, dragon, or monster. Still, even these seemingly confused predictions were often explained on very reasonable grounds: "He (the grownup) knows not to believe in ghosts, but he sees one, so he is really, *really* scared!" Future research needs to more systematically explore how older children and young adults learn to reconcile opposing viewpoints about the ontological status of supernatural creatures from the mixed testimony and evidence they receive from peers, adults, movies, and stories (Harris & Koenig, 2006). For example, parents may claim, "Monsters are not real," yet the older child may read stories or watch movies with very realistic monsters. Indeed, further exploration into a potential developmental transition between 5 and 7 years from *not* believing to believing in the possible existence of the supernatural is warranted.

Future Research and Conclusions

Results of the current study show that between the ages of 3 and 7 years, children increasingly understand that people of different ages can experience different emotions in the same situation. Yet, this still does not clarify whether children believe that dissimilar fear reactions of the two individuals stem from group-specific or person-specific differences (Gnepp, 1989). That is, each scenario contrasted two individuals from separate groups (i.e., grownup vs. child or child vs. infant) but did not contrast two individuals from the same group (i.e., two children, two grownups, or two infants). This conflated the individual with the group, and, as a result, participants' judgments regarding differences between the two story characters cannot conclusively be attributed to either group-specific or person-specific factors. Thus, more needs to be explored about the extent to which children think certain groups may be more or less homogenous in the way they interpret and emotionally react to situations.

Second, previous research has shown that it is not until the age of 7 or 8 that children begin to suggest mental strategies for coping with negative emotions, including fear (e.g., Altshuler & Ruble, 1989; Band & Weisz, 1988). Because the current data reveal that children view fears of imaginary creatures as more causally connected to people's cognitive mental states than fears of real creatures, it is possible that children's initial insights into cognitive strategies for alleviating fear may be in the context of coping with fears of imaginary beings like ghosts and witches. Indeed, it would be interesting to expand on the current study to examine children's suggestions of ways to deal with fears to assess whether young children have stronger knowledge about how to use the mind to cope with fears of the imaginary (e.g., pretending an imagined ghost to be friendly instead of mean) versus real threat situations.

In conclusion, between the ages of 3 and 7 years, children develop more sophisticated knowledge that people of different age groups can experience different intensities of fear in the same situation. Indeed, with increasing age, children demonstrated a stronger appreciation of the mind as mediating between situations and emotions—people's fears depend on their thoughts, beliefs, and knowledge, not just the situation itself—with this knowledge about mental causes of fear being most robust in the context of fears of the imaginary. Future research needs to systematically examine how children's beliefs, questions, and the testimony they hear about what should and should not be feared, as well as what is real and not real, influence the frequency and intensity of their fear in their everyday lives.

Gender and Patterns of Concerned Responsiveness in Representations of the Mother–Daughter and Mother–Son Relationship

Ruth Butler and Rachel Shalit-Naggar
Hebrew University of Jerusalem

Given that girls show more interpersonal concern than boys, it was predicted that more mother–daughter than mother–son dyads would develop a relationship of mutual concerned responsiveness (CR). Two hundred and twenty-six Israeli children (7–8 years old) and 91 mother–child pairs provided narratives of mother–child interactions. At high levels of socioeconomic status (SES), descriptions of child but not maternal concern differed by gender; therefore, more mother–daughter narratives described mutual CR and more mother–son narratives described a nonreciprocal pattern of maternal CR. In a low-SES sample, most mother–daughter narratives described mutual CR, but many mothers and sons described little concern by either partner. Results provided clear evidence of gender differences in mother–child reciprocity and confirmed the importance of examining gender influences in different social groups.

There is still active debate whether and how mother–daughter and mother–son interactions differ in childhood (Leaper, 2002; Lytton & Romney, 1991; Siegal, 1987). In this article, we examined the novel proposal that one significant way in which they differ is in the degree to which both partners show active concern for promoting the welfare of the other and the relationship. Prior studies have not shown gender differences in mother–child mutual responsiveness (Maccoby, 1998). To date, however, researchers have focused mainly on the role of maternal sensitive concern in creating a reciprocal relational system (Kochanska, 1997). In contrast, we examined narrative representations of concern on the part of both mother and child. The first main prediction was that daughters would be described as displaying more active concern than sons. Because mothers tend to display similar levels of concern toward sons and daughters (Leaper, 2002), we thus predicted that more mother–daughter than mother–son narratives would describe a pattern of mutual concerned responsiveness (CR), and more mother–son narratives would describe interactions characterized by concern on the part of the mother alone.

Gender, Concern, and Patterns of Responsiveness in the Mother–Child Relationship

Girls display higher levels of empathic concern, prosocial behavior, and interpersonal responsibility than do boys, across a variety of measures and contexts (see Eisenberg & Fabes, 1998; Maccoby, 1998, for reviews). These gender differences also have implications for boys' and girls' relationships. In their analysis of same-sex peer groups, Maltz and Borker (1982) distinguished between the collaborative, affiliative speech of girls who speak to "create and maintain relationships of closeness and equality" (p. 207) and the competitive, adversarial speech of boys who speak to assert themselves and to maintain an audience. Studies of same-sex friendships in later life have yielded similar findings, whereby women were more oriented than men to understanding and caring for others and to maintaining relational harmony and mutuality (Burke & Fuqua, 1987; Wright, 1982). Moreover, when the sexes meet, women tend to engage more than their male partners in support work that serves to encourage and maintain communication by active listening and sensitive responding (Fishman, 1983; Tannen, 1993). More generally, Bartky (1990) has described heterosexual relationships as characterized by an unequal division of "emotional labor," whereby women invest more effort than do men to promote their partner's emotional welfare.

In a similar vein, some theorists have proposed that the mother–daughter relationship is more likely to

develop along a trajectory of reciprocal responsiveness than the mother–son relationship because mothers are predisposed to create more intimate relations with daughters (Chodorow, 1978; Gilligan, 1996). Analyses of mother–child mutual responsiveness have also emphasized the contribution of the mother and, in particular, the role of maternal sensitivity in inducting children into a system of reciprocity (Kochanska, 1997; Maccoby & Martin, 1983; Maccoby & Parpal, 1985). Originally developed in the context of attachment theory, maternal sensitivity refers to the degree to which the mother is attuned to the child's needs and responds to them in ways intended to promote the child's welfare and to maintain a warm mother–child relationship (Bell & Ainsworth, 1972).

One possibility is that mothers may be more likely to induct daughters into a mutually responsive relationship because they tend to respond more sensitively to daughters than to sons. Most studies have not shown gender differences in the level of observed or reported maternal sensitivity, however (see Leaper, 2002; Lytton & Romney, 1991, for reviews), and the few exceptions have yielded mixed findings as to whether mothers responded more sensitively toward daughters (e.g., Barnett, Kidwell, & Leung, 1998) or sons (e.g., Dodge, Petit, & Bares, 1994). Moreover, studies of children's narrative representations have not shown differences in the degree to which girls and boys themselves described the mother as warm and responsive (Oppenheim, Emde, & Warren, 1997; Solomonica-Levi, Yirmiya, Erel, Samet, & Oppenheim, 2001). Most significantly, in the present context, Maccoby (1998) concluded that studies have not shown gender differences in mother–child mutual responsiveness.

The main objective of the present studies was to examine the proposal that differences in mutual responsiveness in mother–son versus mother–daughter dyads will emerge more clearly than hitherto if one considers possible differences in the contributions of girls and boys to the interactive arena. Specifically, we conceptualized a dimension of child active concern (CAC), analogous in some senses to that of maternal sensitivity, to capture individual differences in the degree to which children respond to the mother's needs and feelings in ways that reflect concern to promote her welfare and to maintain relational harmony. Extrapolating from evidence of early gender differences in prosocial behavior, we predicted that girls will exhibit more such active concern than will boys in the mother–child as in other relationships.

At first sight, this conceptualization may seem inappropriate, given the asymmetrical nature of the mother–child relationship, especially during childhood. Indeed, to date, researchers have defined child responsiveness to the mother mainly in terms of children's positive cooperation and receptive compliance with maternal signals, initiatives, and influence, rather than their proactive concern for the mother and the relationship (Biringen & Robinson, 1991; Kochanska, 1997; Maccoby & Martin, 1983). Studies have shown, however, that already during the first 3 years, some children responded to maternal distress or anger by spontaneously offering comfort or help or trying to repair ruptures in the relationship (Kochanska, Forman, & Coy, 1999; Radke-Yarrow, Zahn-Waxler, Richardson, Susman, & Martinez, 1994; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). Moreover, such responses were more common among girls than boys.

These findings support our proposal that girls are more likely than boys to display active concern within the context of the mother–child relationship. This proposal has clear implications for mutual responsiveness in mother–daughter and mother–son dyads. Specifically, if both mothers and children differ in the degree to which they are oriented to promote the welfare of the other and the relationship, one can theoretically posit four distinct patterns: mutual CR, whereby both mother and child display active concern; maternal CR, whereby the mother but not the child displays active concern; child CR; and no CR by either partner. Moreover, if child gender influences CAC more than it does maternal active concern (MAC), one can predict that more mother–daughter than mother–son dyads will display a pattern of mutual CR, typical also of close female friendships. In contrast, more mother–son dyads should display a pattern of maternal CR, reminiscent of the unequal division of emotional labor that has emerged in studies of other cross-sex interactions.

Although some other theorists have also proposed that mothers are more likely to develop mutually binding relationships with daughters than sons (Chodorow, 1978; Leaper, Anderson, & Sanders, 1998; Maccoby, 1990), Maccoby (1998) concluded that studies have not shown greater mutuality in mother–daughter than in mother–son dyads in childhood. The present analysis suggests that this may have been because researchers did not examine child and thus reciprocal concern. In keeping with prevailing conceptualizations of child responsiveness, Kochanska (1997) defined a "mutually responsive orientation" when dyads show high levels of maternal sensitivity, child committed compliance, and positive mother–child interactions; others have defined reciprocity mainly in terms of shared positive affect (Ainsworth, Blehar, Waters, & Wall, 1978; Dix, 1991). Studies have not shown differences between mother–daughter and mother–son dyads in these kinds of mutual responsiveness (Kochanska, 1997, 2002; Maccoby, 1998). In contrast, we predicted that examining the degree to which both partners are oriented to promote the welfare of the other and the relationship will confirm that more mother–daughter than mother–son dyads will experience a relationship of "mutual CR."

Examining Active Concern and Patterns of CR in the Mother–Child Relationship

The use of projective methods to provide a window on people's emotional and interpersonal worlds has a long history in psychology. For example, in the context of research on the mother–child relationship, studies have shown that children's narratives could be reliably scored for descriptions of maternal sensitive concern that were coherently associated with other measures of child and maternal behavior and adjustment (Oppenheim et al., 1997; Solomonica-Levi et al., 2001). In the present studies, children told stories about pictures in which a mother and her child were depicted in contexts conducive to eliciting concern for the welfare of the other and the relationship from both partners. Thus, in some pictures, the mother was angry, sad, or sick, and in others, the child was sad or angry. Narratives were scored in two ways. First, aggregate measures of maternal and CAC were derived by counting the number of stories in which the mother or the child, respectively, was described as acting to promote the welfare of the other and the relationship. Second, entire protocols were assigned to one or another category of CR based on the degree to which the global impression over all stories and situations was of mutual, maternal, child, or no CR. Children also told a story about an emotionally neutral picture, in which mother and child were depicted sitting on a bench; this story was scored for positive emotional climate. Inclusion of this measure was designed to provide some point of comparison with prior studies of mutual responsiveness. Thus, we anticipated that the well-established association between observational measures of maternal sensitivity and positive mother–child interactions (see Kochanska, 2002; Maccoby, 1998, for reviews) would be replicated also when we examined the relation between representations of MAC in children's stories about negative emotions and representations of the emotional quality of mother–child interactions in their "bench" story.

We report two studies. Participants in Study 1 were children living in a middle-class neighborhood. We focused on 7- to 8-year-olds on the assumption that by this age, children can generate stories without excessive prompting. The first objective was to verify that stories could be reliably scored for descriptions of maternal and CAC and patterns of CR. The second and major objective was to examine the predictions that (a) descriptions of CAC would be more frequent in girls' than in boys' stories, but girls and boys would describe similar levels of MAC and (b) more girls' than boys' protocols would describe a pattern of mutual CR, and more boys' protocols would describe a nonreciprocal pattern of maternal CR. In Study 2, we reexamined these predictions for a larger and more socially diverse sample that included both children and some of their mothers. The main objective was to provide additional validation for our framework by testing the predictions that gender would be related to descriptions of child and mutual concern responsiveness among both children and mothers, at both higher and lower levels of maternal education. Another objective was to examine the further prediction that representations of children and their mothers would be correlated within mother–child dyads.

Study 1

Method

Participants

Participants were 63 children (31 boys, 32 girls, mean age = 97 months, *SD* = 3.62) in two Grade 2 classes in a school serving a middle-class neighborhood in West Jerusalem. Israel has separate school systems for Hebrew-speaking (mainly Jewish) and Arabic-speaking populations; the Hebrew language system is further divided into secular and religious systems. Participants for the present studies were drawn from Hebrew language secular schools. Parents provided informed consent, but the principal did not authorize release of demographic information from students' files.

Instrument

An artist prepared six line drawings of a mother and either a boy or a girl; facial features differed in each; drawings are presented in Figure 1. Five pictures depicted negative emotional states. In each picture, one figure was drawn full-face and one in profile. In two pictures, the mother's face expressed anger or sadness, respectively, and in another two, the child's face expressed anger or sadness. The fifth picture depicted a mother in bed with a thermometer in her mouth. The sixth, "neutral," picture depicted

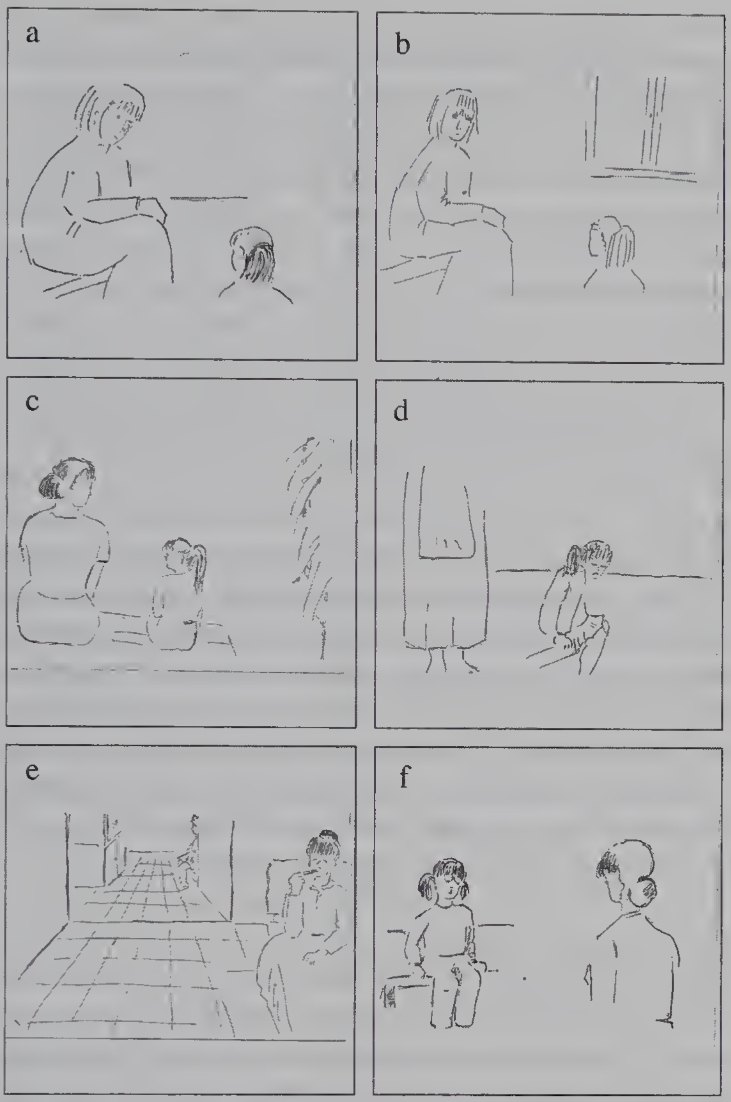

Figure 1. Drawings used to elicit mother–daughter narratives: (a) mother sad, (b) mother angry, (c) bench, (d) child sad, (e) mother sick, and (f) child angry.

a mother and a child in profile sitting on a bench. A pilot study with 15 children at ages 7–8 confirmed that all correctly identified the facial expressions and showed that administration following the sequence mother angry, mother sad, bench, child sad, mother sick, and child angry minimized carryover of themes between stories. We had intended to tape the stories, but the pilot study indicated that the tape recorder distracted the children, increased self-consciousness, and disrupted their narratives. This was not the case when administrators wrote down children's stories; they had no difficulty doing so at a pace that did not seem to affect narrative fluency.

Procedure

The teacher introduced the second author as a student interested in children's stories. The second author invited each child to a side room and presented gender-appropriate pictures in the sequence described above. For each picture, she said, "Here is a mother and her daughter (son). The child is in Grade 2. The mother (child) is angry (or sad, or the mother is sick, or they are sitting on a bench). Tell me a story about the picture: what happened before, what is happening now, what each person is feeling, saying, and doing, and what will happen next." Stories were written down verbatim; probes were used only when major elements were unclear.

Scoring

Pairs of coders who were unaware of the hypotheses scored (a) individual emotion stories, (b) entire protocols, and (c) emotional climate in the bench story. Each pair included one male and one female to control for possible gender influences in interpreting active concern as displayed by girls and boys. A third coder resolved any disagreements.

CAC and MAC. Children's stories about the five emotion pictures (mother angry, sad, sick, and child angry, sad) were each typed on a separate page; stories were scored by picture rather than by child to avoid carryover effects. Two scorers independently scored each story for the presence of CAC and MAC if the target figure acted to promote the other's welfare (e.g., comforted, helped, or tried to solve the other's difficulty) and/or to restore the relationship (e.g., apologized, made reparation). Active concern could be verbal ("The mother said she knew he was sad to miss the school trip, but she'd take him to the zoo when he got better"), nonverbal ("She hugged her mum"), or practical ("He bought his mum a vase instead of the one he broke"). Each story received a score of either 1 or 0 for both CAC and MAC. Agreement coefficients were high for both CAC (from $\kappa = .86$ for mother angry to $\kappa = .96$ for mother sad) and MAC (from $\kappa = .87$ for child angry to $\kappa = .95$ for child sad). Total CAC and MAC scores over all five stories could range from 0 to 5 and were highly correlated between judges, $r(63) = .93$ for CAC and $r(63) = .90$ for MAC.

Patterns of CR. Two scorers each read entire protocols (without the bench story) on the assumption that global readings would best capture patterns of coordination of maternal and child concern across different situations. Scorers assigned protocols to categories of CR after reading the following instructions:

> *Mutual Concerned Responsiveness* is scored when both mother and child are described as displaying an orientation of concern for the other and the relationship, rather than as guided only by their own needs, beliefs, or concerns, and as *acting* to relieve distress, to promote the other's welfare, and

to maintain or restore harmonious relations. This category applies when each partner acts responsively in different stories and/or when stories describe reciprocal concern by both. Mutual empathy (partners feel for one another, but do not act responsively) or compliance (partners just comply with one's another's directives and requests) do not qualify. *Maternal Concerned Responsiveness* is scored when the mother, but not the child is described as acting responsively as described above. Disregard other child behaviors, such as whether they cooperate with or resist maternal initiatives. *Child Concerned Responsiveness* is scored when the child, but not the mother shows active concern. *No Concerned Responsiveness* is scored when neither partner acts responsively. Instead, mother and child ignore the other's distress or ruptures in the relationship, fail to act, or act to influence or discipline the other in keeping with their own wishes, needs, or beliefs.

Scorers were instructed to consider the majority of stories if one differed markedly from the rest and to assign protocols that did not display a clear pattern to a fifth, unclear category. Agreement for assignment to the five categories was high, $\kappa = .92$.

Emotional climate. Two new scorers rated the bench story for emotional climate on a scale anchored at 5 (*very positive: mood is happy, excited*) and 1 (*very negative: mood is angry, fearful, sad*). Only two stories described conflicting emotions in mother and child; both scorers rated these 3. Ratings were highly correlated, $r(63) = .94$ and were averaged across judges.

Results

Gender, Active Concern, and Patterns of CR

As predicted, more girls' than boys' stories were scored for the presence of CAC, $t(61) = 2.10$, $p < .05$, ($M = 2.03$, $SD = 1.45$, and $M = 1.29$, $SD = 1.35$, respectively). In contrast, the effect for gender on descriptions of MAC was not significant ($M_{\text{girls}} = 1.75$, $SD = 1.27$, and $M_{\text{boys}} = 1.58$, $SD = 1.36$). We also predicted that more girls' than boys' protocols would describe a pattern of "mutual CR," and more boys' protocols would describe a pattern of "maternal CR." As expected, an initial analysis for the four categories of CR and the fifth, unclear category yielded a significant association between patterns and gender, $\chi^2(4) = 17.92$, $p < .001$ (see Table 1 for cell frequencies). Follow-up analyses compared the frequency of each pattern (coded 1) versus all other patterns (coded 0). As predicted, more girls' than boys' protocols were scored as mutual CR, $\chi^2(1) = 13.06$, $p < .001$. Indeed, 15 of the 17 such narratives were told by girls, and this was the most frequent category for girls. In contrast, more boys' than girls' protocols were scored as "maternal CR," $\chi^2(1) = 8.22$, $p < .01$, and this was the most frequent category for boys. The association with gender was not significant for the other patterns, but Table 1 shows some tendency for more boys than girls to describe a pattern of child CR.

Table 1

Percentages of Boys' and Girls' Protocols Assigned to Each Pattern of Mother–Child Responsiveness, Study 1

	Boys	Girls	All children
Mutual responsiveness	7	47	27
Maternal responsiveness	36	6	21
Child responsiveness	26	13	19
No CR	19	25	22
Unclear	13	9	11
n	31	32	63

Note. CR = concerned responsiveness

Relations Between Representations

As expected, representations of MAC were significantly correlated with positive emotional climate in the bench story for both girls, $r(32) = .51$, $p < .01$, and boys, $r(31) = .37$, $p < .05$. The level of positive emotional climate did not differ significantly by gender. In contrast, descriptions of CAC and MAC were significantly correlated among girls, $r(32) = .41$, $p < .05$, but not boys, $r(31) = -.23$; these correlations differed significantly, $z = 2.58$, $p < .01$. This was the case also for the association between CAC and positive emotional climate in the bench story, $r(32) = .42$, $p < .05$ for girls, and $r(31) = -.10$ for boys, $z = 2.08$, $p < .05$.

Discussion

Children's stories could be reliably scored for representations not only of MAC but also of CAC and patterns of CR. Most significantly, the results supported the predictions that more girls than boys would describe a relationship of reciprocal concern because of gender differences in representations of CAC. In keeping with results from studies based on observational measures of maternal sensitivity (Biringen et al., 1999; Kochanska, 1997) or a more established procedure for eliciting and scoring children's narratives (Oppenheim et al., 1997), boys and girls did not differ in the frequency with which they described the mother as acting to promote the welfare of the child and the relationship. In contrast, girls described more instances of CAC than boys. Thus, far more girls than boys described a relationship of "mutual CR" in which both partners displayed active concern, and more boys than girls described a nonreciprocal pattern of "maternal CR."

These results are quite exciting in view of Maccoby's (1998) conclusion that studies have not shown greater reciprocity in mother – daughter than in mother – son dyads in childhood. Some additional findings provided further support for our interpretation that gender is related to some, more than other, kinds of mother – child reciprocal responsiveness. In keeping with results from the studies of reciprocal positive affect reviewed by Maccoby (1998), gender did not influence descriptions of positive emotional climate in the bench story or the positive association between positive climate and representations of maternal concern. This similarity with prior findings inspires confidence in our narrative measures. In contrast, although studies have shown that maternal sensitivity was associated with committed compliance in children of both sexes (Kochanska, 1997, 2002), representations of maternal and child concern were positively correlated only in girls' narratives. Thus, there might be differences between girls and boys not only in the level of child concern but also in the degree to which children respond to maternal concern with both concern and compliance or mainly with compliance alone.

It is premature to discuss these results further because Study 1 had several limitations that we addressed in Study 2. First, the sample was small and socially homogenous. Second, claims about gender differences in the mother – child relationship necessitate incorporation also of the mother's perspective. Third, Study 1 did not provide any external validation for children's representations. Fourth, our interpretation that gender might moderate the relation between maternal and child concern more than it does the relation between maternal concern and child committed compliance must be treated with caution because we did not include a measure of committed compliance.

Study 2

In Study 2, we examined representations of mother – child interactions in a larger, socially diverse sample that included both children and some of their mothers. The first objective was to examine whether the gender differences in children's representations of child and mutual CR would be replicated at both higher and lower levels of socioeconomic status (SES), as determined by maternal education. This endeavor is important because most studies of gender influences in the mother – child relationship have examined middle-class samples (see Leaper, 2002; Leaper & Smith, 2004; Leaper et al., 1998, for reviews). Interestingly, the few studies that have shown gender differences in maternal sensitivity targeted low-SES groups, but these studies have yielded mixed findings as to whether mothers behaved more sensitively toward sons (Biringen et al., 2000; Dodge et al., 1994) or daughters (Barnett et al., 1998). Other studies of low-SES groups in both North America and Israel did not show any effect of child gender on maternal sensitivity, however (Kiang, Moreno, & Robinson, 2004; Solomonica-Levi et al., 2001). In contrast with these mixed findings, gender differences in children's prosocial behavior have emerged across a wide range of social and cultural groups (LaFreniere et al., 2002; Whiting & Edwards, 1988), and girls responded more empathically to maternal distress than boys in the only such study that targeted a low-SES sample (Kiang et al., 2004). Thus, there were grounds for anticipating that gender would affect representations of child, more than MAC at both high and low levels of maternal education, and thus that the gender differences in patterns of CR reported in Study 1 would be replicated for both social groups.

The second objective was to examine the predictions that mothers will also describe girls as displaying more active concern than sons and will be more likely to describe a relationship of mutual CR with daughters and a relationship of maternal CR with sons. Most mothers were asked to describe recent situations in which the mother and target child were present; the mother was angry, sad, or ill; the child was angry or sad; and, for the neutral cue, a situation where both mother and child were present. The aim was to elicit rich and detailed descriptions of actual mother – child interactions, but we also had some concern that this procedure might be more likely than less direct methods to bias mothers to describe their relationship with their child too positively. Thus, some mothers were asked to tell stories about the pictures given to children; some of these mothers also described actual events. This aspect of the design enabled us to compare descriptions of MAC and CAC and patterns of CR both between mothers given different procedures and within mothers who responded to both.

No studies have examined maternal reports of child or mutual responsiveness as defined here, but there is some prior evidence that mothers rated daughters as more empathic and helpful than sons (Eberly & Montemayor, 1998; Hastings, Zahn-Waxler, Robinson, Usher, & Bridges, 2000). In addition, analyses of the mother–child relationship as a system of reciprocity (Kochanska, 1997; Maccoby & Martin, 1983) imply congruence between partners' perspectives and experiences. If boys and girls differ in their descriptions of CAC and patterns of CR, one would expect child gender to be related to maternal representations in similar ways. The third objective was to examine the related prediction that children's and mothers' representations of concern will be correlated within mother–child dyads. If the results support this prediction, they will contribute to addressing another limitation of Study 1 by providing some external validation for children's representations. We also examined the stability of children's representations by retesting some of the children after about a year.

The fourth objective was to examine whether gender moderates the relation between maternal and child concern more than it does the relation between maternal concern and child committed concern. Maternal protocols were scored both for CAC and for the degree to which the mother described the child as cooperating and eagerly complying with her initiatives and directives. Following prior findings and the results of Study 1, we predicted that representations of maternal concern would be associated with descriptions of child committed compliance for both boys and girls (Kochanska, 1997, 2002) but would be associated with representations of CAC only for girls.

Method

Participants

The child sample included 83 boys and 80 girls (mean age at testing = 95 months, *SD* = 6.16) in one Grade 1 and six Grade 2 classes in three Hebrew language secular schools in a large city in Israel. All schools were defined by the Israeli Ministry of Education as serving similar socially diverse populations with a mix of about 60% students of middle to high SES and about 40% of low SES. Parents were sent a description of the study and asked whether they agreed (a) that their child participate in the study and (b) that schools release their phone number so that we could also invite mothers to participate. Data for children were collected in their schools; the procedure was readministered in two classes after 11 months to 20 boys and 19 girls (mean age = 9 years 1 month). Of the 140 mothers who agreed that we could contact them, 49 refused to participate, repeatedly canceled meetings, or moved to other towns. Data from the other 91 mothers (45 mothers of boys, 46 mothers of girls, mean age = 38 years 1 month) were collected in home visits. Mothers provided background information for the 91 children in the mother–child sample; 84 were living in two-parent families. Schools provided information about maternal education and child age and birth order for the other 72 children. The child and mother–child samples, broken down by child gender and low (12 or fewer years) versus high (at least some higher education) levels of maternal education, are presented in Table 2. Sample comparability was maintained also when we compared the proportions of first- versus later-born children.

Procedure

Data were collected by five female students who were unaware of the study's aims and hypotheses. Children told stories about pictures during school hours, as described for Study 1. Data from mothers were collected in their homes up to 9 months later by a student who had not collected data from that mother's child. The student explained that we had asked children to make up stories about mothers and children and were also interested in how mothers describe things that happen between mothers and children. Mothers were randomly assigned to either a description or a story condition. Each mother in the description condition was asked to recall recent situations in which she and the target child were present and she was angry, she was sad, the child was sad, the mother was sick, and the child was angry. For the neutral cue, she was asked to recall a recent event when mother and child were together. Mothers were encouraged to describe each situation in detail: the setting and background; what each person did, felt, and said; and how it ended. Mothers in the story condition were asked to tell stories about the pictures

Table 2
Participants in Child and Mother–Child Samples of Study 2, by Maternal Education and Gender

	Maternal education			
	High		Low	
	Boys	Girls	Boys	Girls
Child sample	45 (28)	51 (31)	38 (23)	29 (18)
Mother–child sample	26 (29)	29 (32)	19 (21)	17 (19)

Note. Percentages of each sample are in parentheses.

given to children. They were told that each picture showed a mother and her 8 (or 7)-year-old daughter or son, depending on the age and sex of the participating child. Five mothers in this condition said that they did not like to make up stories and were asked to describe events instead. Overall, 49 mothers provided descriptions and 42 told stories; 19 of the latter were also asked to describe actual events. Students had no difficulty writing down mothers' narratives verbatim. Finally, mothers provided information about parents' education and marital status and any medical, psychological, economic, or other problems in the family or the target child.

Scoring

Each measure was scored by different pairs of judges who were all unfamiliar with the hypotheses and did not participate in data collection. Members of each pair independently scored a number of narratives to establish reliability and then divided remaining narratives between them. Different pairs scored stories and descriptions for mothers who provided both.

Active concern and positive emotion. Each story or description about negative emotions was scored for the presence of active concern by each partner, as described for Study 1. Agreement coefficients were calculated separately for CAC and MAC after two pairs of judges scored 50 stories about each situation from child or mother protocols, respectively. Agreement ranged from $\kappa = .85$ for mothers' descriptions of MAC in the mother angry situation to $\kappa = .96$ for both children's and mothers' descriptions of CAC in the mother sick situation. Total CAC and MAC scores over all five stories were highly correlated between scorers, $r(50) = .92$ and $r(50) = .94$ for children, and $r(50) = .92$ and $r(50) = .93$ for mothers. Two new scorers rated narratives about the neutral cue for positive emotional climate with high agreement, $r(50) = .94$ for children and $r(50) = .93$ for mothers.

Patterns of CR. Protocols were assigned to one of four categories of CR or to a fifth, unclear category, as described for Study 1. Agreement coefficients for 40 randomly selected child protocols and 40 randomly selected maternal protocols were $\kappa = .92$ and $\kappa = .90$, respectively.

Child committed compliance. The first author identified stories or descriptions as relevant for scoring if the mother described attempts to influence the child by making suggestions, giving advice, or directing the child to behave in a particular way. Following Kochanska (1997), two scorers rated the 234 relevant narratives for child compliance on a 3-point scale, where a score of 3 reflected eager and committed compliance or cooperation, a score of 2 reflected compliance after pressure or repeated attempts, and a score of 1 reflected noncompliance; stories that did not describe the child's response were coded 0. We could not assess internal reliability because in most protocols at least one story was irrelevant or did not describe the child's response. Final scores for committed compliance were computed as the mean over all relevant stories and were highly correlated between scorers, $r(91) = .89$, $p < .001$.

Results and Discussion

Results are reported in three sections that examine (a) effects of gender and maternal education on representations of concern for the 163 children, (b) effects for the 91 mothers, and (c) relations among representations of concern and compliance in the 91 dyads.

Child Data

Representations of active concern and patterns of CR. We predicted that the effects of child gender on representations of CAC and patterns of CR reported in Study 1 would be replicated at both high and low levels of maternal education. As expected, a 2 (gender) × 2 (maternal education) analysis of variance (ANOVA) for children's representations of child concern yielded only a significant main effect for gender, $F(1, 159) = 12.24$, $p < .001$ ($M_{\text{girls}} = 1.97$, $SD = 1.30$ and $M_{\text{boys}} = 1.25$, $SD = 1.34$). In contrast, a 2 (gender) × 2 (maternal education) ANOVA for representations of maternal concern yielded unanticipated main effects for gender $F(1, 159) = 5.13$, $p < .05$, and maternal education, $F(1, 159) = 5.65$, $p < .05$, which were qualified by a significant interaction effect, $F(1, 159) = 7.16$, $p < .01$, $MSE = 1.51$. Follow-up analyses indicated that these effects derived from the low levels of maternal concern described by boys in the low maternal education group (see Table 3 for cell means). Girls described significantly more instances of maternal concern than did boys in the low, $F(1, 159) = 10.32$, $p < .001$, $MSE = 1.51$, but not the high maternal education group. In addition, representations of maternal concern were significantly more frequent at high than at low levels of maternal education among boys, $F(1, 159) = 13.53$, $p < .001$, $MSE = 1.51$, but not girls.

The results for patterns of CR were also more complex than anticipated because a 5 (pattern) × 2 (gender) × 2 (maternal education) loglinear analysis

Table 3

Means for Children's and Mothers' Representations by Maternal Education and Gender, Study 2

	High maternal education				Low maternal education

Note. CAC = child active concern; MAC = maternal active concern.

yielded a significant third-order effect, $\chi^2(4) = 8.68$, $p < .05$ (see Table 4 for cell frequencies). Follow-up 2 × 2 × 2 loglinear analyses for each pattern, with the target pattern coded 1 and all other patterns coded 0 contributed to clarifying this effect. As predicted, the mutual CR pattern was significantly associated only with gender, $\chi^2(1) = 18.09$, $p < .001$, and was described far more frequently by girls (49%) than by boys (16%). In addition, the tendency noted in Study 1 for more boys than girls to describe a relationship in which only the child displayed active concern was significant for the larger sample of Study 2, $\chi^2(1) = 8.20$, $p < .01$; 16% of boys' protocols but only 3% of girls' protocols were scored as child CR. The third-order effect for Pattern × Gender × Maternal Education was significant for both the maternal CR, $\chi^2(1) = 4.92$, $p < .05$, and the nonresponsive pattern, $\chi^2(1) = 3.97$, $p < .05$. Further analyses and the frequencies presented in Table 4 showed that results for the high maternal education group replicated those of Study 1 because more boys than girls described a pattern of maternal CR, $\chi^2(1) = 6.25$, $p < .05$, and gender did not affect the frequency of the nonresponsive pattern. In contrast, in the low maternal education group, boys were no more likely than girls to describe a pattern of maternal CR but were more likely to describe the nonresponsive pattern, $\chi^2(1) = 4.63$, $p < .05$.

Table 4

Percentages of Children's Protocols Assigned to Each Pattern of Mother–Child CR by Maternal Education and Gender, Study 2

	High maternal education		Low maternal education		
	Boys	Girls	Boys	Girls	All
Mutual CR	18	47	11	41	29
Maternal CR	36	14	16	24	22
Child CR	13	4	16	0	9
No CR	24	31	50	24	32
Unclear	9	4	8	10	8
n	45	51	38	29	163

Note. CR = concerned responsiveness.

Emotional climate in the bench story. A 2 (gender) × 2 (maternal education) ANOVA yielded an unanticipated effect for gender, $F(1, 159) = 6.53$, $p < .05$ ($M_{\text{girls}} = 3.54$, $SD = 1.34$ and $M_{\text{boys}} = 3.01$, $SD = 1.36$) and a marginally significant effect for maternal education ($p < .10$). The means presented in Table 3 indicate that both effects derived mainly from the low level of positive emotion described by boys in the low maternal education group. Thus, to summarize, results for the high maternal education group replicated those for the similar sample of Study 1, and results for girls were similar in both social groups. In contrast, the boys in the low maternal education group described lower levels than did the girls not only of child concern but also of maternal concern and positive emotion. Low-SES boys were also less likely than were boys in the high maternal education group to describe a pattern of maternal CR and were more likely to describe a relationship in which neither partner displayed active concern.

Stability of children's representations. Measures for children who were retested after 11 months were quite stable, $r(39) = .45$, $p < .01$ for CAC, and $r(39) = .58$, $p < .001$ for MAC. Protocols were assigned to the same category of CR in 79% of cases.

Mother Data

Representations of active concern and patterns of CR. Mean levels of CAC and MAC did not differ significantly in descriptions versus stories, and these procedures yielded similar distributions of patterns of CR (33% mutual, 27% maternal, 4% child, 33% nonresponsive, and 4% unclear for descriptions and 33%, 19%, 2%, 10%, respectively, for stories). Protocols of mothers who provided descriptions and stories were assigned to the same category of CR in 90% of cases. These results allayed our concern that descriptions might be more positively biased than stories and justified combining data from both procedures. We analyzed descriptions for mothers who also told stories.

Overall, the results for mothers were consistent with the initial predictions. A 2 (gender) × 2 (maternal education) ANOVA for maternal descriptions of CAC yielded only the predicted significant main effect for gender, $F(1, 87) = 17.42$, $p < .001$; mothers described more instances of active concern by daughters ($M = 1.84$, $SD = 0.98$) than by sons ($M = 1.09$, $SD = 0.90$). The analysis for representations of maternal concern did not yield any significant effects involving gender or maternal education, but the means presented in Table 3 show that low-SES mothers of sons tended to describe fewest instances of both MAC and CAC.

Few maternal protocols were scored as child CR or unclear (see Table 5 for cell frequencies). Loglinear modeling of associations between gender, maternal education, and the three other patterns ($n = 82$) retained only the predicted association between patterns and gender, $\chi^2(2) = 10.58$, $p < .01$. Follow-up analyses confirmed that more mothers of daughters (54%) than sons (20%) described a relationship of mutual CR, $\chi^2(1) = 10.30$, $p < .001$, but the predicted association between gender and the maternal CR pattern was only marginally significant ($p < .10$). As was the case also for children, this pattern was more frequent in mother–son than in mother–daughter protocols in the high maternal education group, but in the low maternal education group, mothers of boys were no more likely than mothers of girls to describe a pattern of maternal CR and were more likely to describe a nonresponsive relationship (see Table 5 for cell frequencies).

Positive emotional climate and child compliance. Positive emotion did not differ significantly by gender or maternal education, but a 2 (gender) × 2 (maternal education) ANOVA for maternal descriptions of child compliance yielded a significant main effect for gender, $F(1, 87) = 4.17$, $p < .05$. Overall, mothers described girls as more cooperative and compliant ($M = 2.53$, $SD = 0.66$) than boys ($M = 2.26$, $SD = 0.69$), but the means presented in Table 3 indicate that this difference was marked only in the low maternal education group.

Relations Among Representations in Mother–Child Dyads and Narratives

Patterns of CR within mother–child dyads are presented in Table 6. Although data for mothers and children were collected in different arenas, with a time lag of up to 9 months, there was considerable congruence between their representations. Thus, for each of the three relatively frequent patterns of mutual, maternal, and no CR, mother and child protocols were assigned to the same category in over 70% of dyads. Low expected cell frequencies precluded statistical analysis, but the correlations presented in Table 7 confirm that equivalent measures derived from children's and mothers' narratives were significantly correlated in both mother–son and mother–daughter dyads. This was the case both for descriptions of CAC and MAC and for descriptions of positive emotional climate; no correlations differed significantly at high versus low levels of maternal education.

The correlations presented in Table 7 also confirmed that descriptions of maternal and child concern were significantly correlated in mother–daughter but not mother–son narratives and dyads; the difference between correlations was significant for children's narratives, $z = 2.22$, $p < .05$. In keeping with the results of Study 1, positive emotional climate was significantly correlated with active concern in mother–daughter but not mother–son narratives

Note. The first letter denotes whether the measure was derived from child or maternal narratives. CAC = child active concern; MAC = maternal active concern; PE = positive emotion; CCP = child committed compliance.
$*p < .05$. $**p < .01$. $***p < .001$.

and dyads. In contrast, maternal concern was similarly and usually significantly correlated with descriptions of both child compliance and positive emotional climate in all narratives and dyads. Despite the different correlates of child concern and child committed compliance, these kinds of responsiveness were significantly correlated for both girls and boys.

Supplementary Analyses

Representations of active concern were not significantly associated with birth order, number of siblings, or maternal reports of problems in the family or child, and the number of problems reported did not differ by gender or maternal education. Although girls might be more interested than boys in socioemotional themes, gender was not related to the word count of children's stories, and this measure of verbal fluency was not significantly correlated with either MAC, $r(163) = .05$ or CAC, $r(163) = .11$.

General Discussion

Results from two studies provided novel evidence of gender differences in mother – child reciprocal responsiveness and suggested that these were due in large part to the differential contributions of girls and boys to the interactive arena. Children and mothers described girls as acting more often than boys to alleviate maternal distress and to maintain or restore relational harmony. In contrast, with the exception of children in the low-SES sample of Study 2, participants did not describe mothers as showing more concern toward daughters than sons. Thus, far more mother – daughter than mother – son narratives described a relationship of "mutual CR" reminiscent of the reciprocal care and concern that has emerged in studies of close female friendships (Burke & Fuqua, 1987; Wright, 1982).

We examined representations rather than behaviors, but studies have shown consistent relations between narrative and observational measures of attachment and maternal sensitivity (Bar-Haim, Sutton, Fox, & Marvin, 2000; Bretherton, Ridgeway, & Cassidy, 1990; Solomonica-Levi et al., 2001) and between child narrative, mother report, and behavioral measures of children's concern for others (Davidov & Grusec, 2006). The results of Study 2 confirmed further that child representations of active concern and patterns of CR were consistently associated with equivalent measures derived up to 9 months later from their mothers, most of whom provided detailed descriptions of actual interactions with the child. Thus, we can be fairly confident that the narratives of both children and mothers described important aspects of their experiences and behaviors in the mother – child relationship.

Many studies have shown that females tend to show greater interpersonal care and responsibility than do males, as peers, friends, spouses, and parents (Maccoby, 1998) and also in early interactions with the mother (Kiang et al., 2004; Kochanska et al., 1999; Radke-Yarrow et al., 1994; Zahn-Waxler et al., 1992). Interestingly, however, prior studies have not examined the implications of these differences for the development of reciprocity in mother – daughter and mother – son dyads. Rather, analyses of mother – child mutual responsiveness have emphasized the role of maternal sensitive concern in creating a relational system in which children of both sexes are motivated to cooperate and comply with maternal initiatives, and influence, and engage with the mother in mutually enjoyable interactions (Biringen & Robinson, 1991; Kochanska, 1997, 2002; Maccoby & Martin, 1983). Against this background, our main contribution was in conceptualizing active concern as a feature not only of the mother but also of the child and of the interactions between them. This approach yielded a novel framework for characterizing the mother – child relationship in terms of patterns of CR and provided the clearest empirical evidence to date that mother – daughter dyads are more likely than mother – son dyads to develop a relationship of mutual care and concern already in childhood (Chodorow, 1978; Jordan & Surrey, 1986).

These results are consistent with our proposal that other researchers did not find gender differences in mother – child reciprocity because they examined different kinds of child and mutual responsiveness. Representations of child concern and committed compliance were moderately correlated, however, and girls tended to score higher than boys also on committed compliance. This was the case also in studies of mother – child mutually responsive orientation (e.g., Kochanska, 1997; Kochanska, Coy, & Murray, 2001). Further studies might address the intriguing possibility that Kochanska's strategy of assessing mutually responsive orientation as an aggregate of child committed compliance, maternal sensitivity, and shared positive affect might mask possible differential contributions of girls and boys to the development of this kind of mother – child reciprocity as well. However, although we emphasized differences in the level of concern that girls and boys bring to interactions with the mother, our results also revealed another way in which gender seemed to influence mutual concern more than it does other kinds of mother – child reciprocity. In keeping with prior findings (see Kochanska, 2002; Maccoby, 1998, for reviews), associations between maternal responsiveness, child willing compliance, and positive affect were similar and significant across all narratives and dyads. Therefore, boys did not fail to respond to maternal concern, and sensitive parenting seemed to orient children of both sexes to interact positively and cooperatively with sensitive mothers. In contrast, representations of maternal and child concern were significantly associated only in mother – daughter narratives and dyads. Thus, mutual responsiveness in mother – daughter and mother – son interactions differed not only because girls showed more active concern, and to some extent compliance than boys, but also because girls seemed more likely to reciprocate maternal concern in kind.

There is some prior evidence that links between parenting and children's empathy were more consistent in mother – daughter than in mother – son dyads (Eisenberg & Fabes, 1998; Hastings, Utendale, & Sullivan, 2007; Zahn-Waxler, Cole, & Barrett, 1991; but see Kiang et al., 2004, for a recent exception). Our data cannot explain why this might be the case, but one possibility is that mothers induct daughters more than sons into a relationship of reciprocal concern. Responsive mothering is crucial in creating a system in which children are receptive to maternal influence, but relations between maternal sensitivity and child outcomes are moderated by parenting goals and practices (Grusec & Goodnow, 1994; Hastings & Rubin, 1999), some of which may differ for boys and girls. Specifically, mothers seem to value and strive to socialize willing compliance in both sons and daughters (Hastings & Grusec, 1998), but gender stereotypes, mother's prior social histories, and early gender differences in sociability might converge in orienting mothers to value, expect, and socialize active concern for the mother in girls more than in boys (see also Brody, 1999). If mothers expect daughters to show more concern than sons, this could also explain why maternal descriptions of mother – child emotionally positive interactions were significantly correlated with their descriptions of girls' but not boys' active concern. Few studies have directly examined maternal socialization of care and concern, but mothers do seem to talk to and discipline young children in ways that direct girls more than boys to consider other people's perspectives and feelings and to assume responsibility for alleviating distress and repairing relationships (Brody, 1999; Fivush, 1993; Leaper et al., 1998; Smetana, 1989). Any such divergence in reciprocal concern in mother – daughter as compared with mother – son dyads should then increase as gender differences in relational styles are reinforced in the same-sex peer group (Maccoby, 1990).

Although the school-age children in our samples already had considerable peer experience, other scholars have also proposed that the mother – child relationship plays a role in orienting girls to display care and concern in relationships and orienting boys to cooperate with, but not necessarily reciprocate concern in their interactions with, females (Brody, 1999; Robinson, Little, & Biringen, 1993). Indeed, the results for the high-SES samples confirmed that more mother – son than mother – daughter narratives described a pattern of maternal CR reminiscent of the unequal division of support work that has emerged in studies of cross-sex relationships in later life (Fishman, 1983; Tannen, 1993). Interestingly, boys were also more likely than girls to describe the other nonreciprocal pattern, in which only the child showed active concern. The intriguing implication that child concern develops in response to maternal concern in girls, but may develop in response to maternal deficits in at least some boys, must be treated with caution because, overall, both boys and girls who described unconcerned mothers also described unconcerned children. In support, however, Radke-Yarrow et al. (1994) found that maternal depression was necessary to elicit caring behavior in sons but undermined care for the mother in girls.

Finally, we must address the unanticipated interactions between gender and SES, which we assessed in terms of high versus low levels of maternal education. Descriptions of concern and compliance in mother – daughter interactions did not differ at higher and lower levels of SES, but a striking 50% of low-SES boys told stories in which neither mother nor child showed concern for the other or the relationship. Mothers' narratives differed significantly only by gender, but low-SES mothers of sons also tended to describe low levels of maternal and child concern and were most likely to describe a nonresponsive relationship. Descriptions of emotional climate and child committed compliance were also most negative in this group. A close reading of maternal protocols indicated further that low-SES mothers of sons were most likely to spontaneously complain that the child did not listen to her and was hard to talk to.

If these sons were relatively uncommunicative and resistant to maternal influence, they might also have evoked less sensitive, more power-assertive parenting, which tends to further undermine children's responsiveness to gentler forms of influence to create an escalating cycle of aversive interactions (Campbell, Pierce, Moore, & Marakovitz, 1996; Sanders, Dadds, Johnston, & Cash, 1992). Conversely, low-SES mothers and daughters, at least in our sample, may have maintained close and positive relations at least in part because they talked more. In their comprehensive study of British working-class and middle-class mothers and their 7-year-old sons or daughters, Newson and Newson (1976) found somewhat similar patterns whereby mothers and daughters chatted to and confided in one another in both social groups, middle-class sons talked to their mothers but were less likely than girls to invite and receive maternal confidences, and mother – child interactions were most distant and aversive in working-class mother – son dyads. Of particular interest, working-class mothers attributed these negative interactions mainly to the growing influence of fathers and male peers whom they saw as encouraging their sons to resist and disparage maternal influence and companionship.

We must be cautious in generalizing from our results because of the small sample, the sometimes insignificant trends, and the mixed results of some other studies. For example, maternal sensitivity tends to be lower in low-SES samples than in high-SES samples (see Conger & Dogan, 2007; Hoff, Laursen, & Tardiff, 2002, for reviews), but in our Study 2, this was the case only for mothers of boys. In addition, as we reviewed in an earlier section, studies that targeted low-SES samples have yielded mixed findings as to whether mothers behaved more sensitively toward sons or daughters, and Eisenberg (1996) reported more aversive conflicts in low-SES mother – daughter than mother – son dyads. Moreover, although our discussion focused on unresponsive low-SES mother – son dyads, it is important to emphasize that about a quarter of the narratives in other groups also described unresponsive and usually aversive interactions. Finally, reviews have identified both SES (Hoff et al., 2002) and gender (Leaper & Smith, 2004; Leaper et al., 1998) influences on mother – child talk, but few studies have examined both sources of influence. Thus, further research is necessary to examine our tentative interpretation that low-SES mother – son dyads displayed such low levels of concern at least in part because boys growing up in traditional working-class cultures might be least likely to listen to their mothers' "voice."

Before we address some additional implications, it is important to note several limitations of our studies. First, the narratives provided rich and coherent information as to how representations of concern and other aspects of mother – child interactions were related within individual protocols and mother – child pairs, but it is important to validate our framework and results for additional, preferably behavioral, measures of concern and compliance. Second, the results for high-SES samples provided consistent support for our proposal that there are gender differences in child, more than in maternal concern, but one must be cautious in drawing conclusions from null results. Third, we did not consider other arenas that might influence school-age children's CR in the mother–child relationship. Peers and fathers may be more influential than mothers in sex-role socialization and may play a particularly important role in fostering an orientation of care and concern in girls and orienting boys to construct a sense of self based in part on the repression of such feminine qualities (Gilligan, 1996; Maccoby, 1998; Ruble & Martin, 1998; Siegal, 1987). Fourth, our interpretation that any such influences might be particularly marked in more traditional working-class cultures must be treated with caution in view of the small sample and the mixed results of some other studies. Longitudinal, multimethod studies that would examine the development and correlates of child and reciprocal concern between early and middle childhood in different social groups would contribute to addressing these limitations.

Focusing on levels and patterns of coordination between maternal and CAC shed new light on the contribution of the child to reciprocal responsiveness in mother–son and mother–daughter dyads and revealed some intriguing continuities in the ways in which boys and girls behave with the mother and in later relationships with females. Our concepts and results also suggest some interesting directions for further research. Distinguishing between global maternal sensitivity and specific practices more directly relevant to the induction of concern might reveal more consistent linkages than hitherto between parenting and the development of empathic concern in both boys and girls (see also Davidov & Grusec, 2006; Eisenberg, Fabes, Carlo, Speer, & Switzer, 1993). Our framework and methods might also contribute to understanding the joint influences of both child and parent gender. For example, gender differences in concern imply that fathers will be less likely than mothers to develop a relationship of mutual CR, especially with sons. In support, Maccoby (1998) reported that mother–daughter pairs were most successful and father–son dyads were least successful on a task of referential communication because of gender differences in the referential skills of both children and parents. Our narrative procedures might also be well suited, however, to reveal other ways in which fathers might promote mutually binding relations with their children.

Our distinctions between different patterns of CR might also contribute to reconciling approaches that consider empathic concern for the mother to be an important component of prosocial behavior (Hastings et al., 2000; Kiang et al., 2004) with approaches that consider child concern for the mother to be rather maladaptive (Freud, 1946; Winnicott, 1965). This might be the case if concern develops in response to poor mothering or is expressed in age-inappropriate ways. However, most stories scored for CAC described children who cared about, rather than taking care of the mother, and most narratives that described concerned children also described concerned parents. Thus, the role of children's concern in their social and emotional adjustment should depend mainly on the degree to which children also experience the mother as concerned and sensitive. Further studies might, however, address the possibility that as long as interpersonal care and concern are viewed mainly as "women's work," high levels of concern for the mother might be more problematic for boys than for girls. Thus, such concern might be more likely to develop in response to maternal deficits in boys (Radke-Yarrow et al., 1994) and is less congruent with the relational style of the male than the female peer group (Maccoby, 1998; Maltz & Borker, 1982). Last, but not least, our results highlight the importance of examining gender patterns in the mother–child relationship in different social and cultural groups.

Development of Feedforward Control in a Dynamic Manual Tracking Task

Dominique van Roon, Karen Caeyenberghs,
and Stephan P. Swinnen
Katholieke Universiteit Leuven

Bouwien C. M. Smits-Engelsman
Katholieke Universiteit Leuven, Avans+, University for Professionals, and Radboud University Nijmegen

To examine the development of feedforward control during manual tracking, 117 participants in 5 age groups (6 to 7, 8 to 9, 10 to 11, 12 to 14, and 15 to 17 years) tracked an accelerating dot presented on a monitor by moving an electronic pen on a digitizer. To remain successful at higher target velocities, they had to create a predictive model of the target's motion. The ability to track the target at higher velocities increased, and the application of a feedback-based step-and-hold strategy decreased with age, as shown by increases in maximum target velocity and decreases in number of stops between ages 6–7 and 8–9 and between ages 8–9 and 10–11. The ability to exploit feedforward control in a dynamic tracking task improves significantly with age.

According to von Hofsten (1993, 2007) the development of action is a matter of acquiring prospective control. When interacting with the environment, actions have to become increasingly future oriented. Predictions have to be made about what is going to happen next. With increasing age, these predictions become more and more accurate because the processing of appropriate predictive perceptual information in the environment becomes faster. In addition, children learn the rules and regularities that govern events and are able to cognitively represent such events. Visually or manually tracking fast-moving objects are examples of tasks in which prospective (or feedforward) control is indispensable.

The development of predictive *visual tracking* has been studied extensively in the past (e.g., Bertenthal, Longo, & Kenny, 2007; Gredebäck, von Hofsten, Karlsson, & Aus, 2005; von Hofsten & Rosander, 1997). Even very young infants in the 1st year of their lives appear to be able to predict object motion when visually tracking this object. In addition, they are able to use the past history of a moving object to build an internal representation of the object's motion, which can be used to predict when and where the object will reappear after a temporary occlusion (e.g., Gredebäck & von Hofsten, 2004; Spelke, Katz, Purcell, Ehrlich, & Breinlinger, 1994). Also, when a child wants to grasp a moving object, he or she has to be able to predict its future location and anticipate to that. Infants as young as 8 months appear to be able to catch objects moving at 120 cm/s (von Hofsten, 1983).

Although visual pursuit of a moving target appears to develop very early in life, *manually tracking* a moving target appears to develop later. Although manually tracking a visible target always requires visual tracking, and the term visuomanual tracking is therefore used in many studies, we will use the term manual tracking to prevent confusion. Several developmental studies on manual tracking were performed previously. Some investigators used a rotary pursuit apparatus (e.g., Davol, Hastings, & Klein, 1965; Dunham, Allan, & Winter, 1985), in which a participant had to maintain contact between a predictably rotating target spot and a handheld stylus. In other studies, the task was to track a target light, projected on a vertical screen and moving predictably along a straight line, by moving the splinted forearm in the horizontal plane (e.g., Mounoud, Viviani, Hauert, & Guyon, 1985; Zanone, 1990). Van der Meulen, Gooskens, Willemse, Denier van der Gon, and Gielen (1990) used a horizontal rail along which a handle could be moved. Two arrays of light emitting diodes (LED) (indicating the target, which moved unpredictably, and the handle position) were visible above the track. In our tracking study, a digitizing tablet was used. Participants had to move an electronic pen on this tablet to track a circularly moving target presented on a computer monitor in front of them.

Support for this study was provided through a grant from the Research Programme of the Research Foundation—Flanders (FWO, Levenslijn # 7.0004.05). D. van Roon was funded by a visiting postdoctoral fellowship of the Research Foundation—Flanders (FWO, GP.026.06N) and the Research Fund of Katholieke Universiteit Leuven (F/06/024).

Not only in visual tracking but also in manual tracking, the adequate formation of a predictive model of the target's motion is of the utmost importance, especially when the target is moving fast as the online use of feedback is impossible under these circumstances. To be successful, the future motion of the target has to be predicted and anticipated in the movements of the arm. Because manual tracking of a moving object is much more complex than visual tracking, the development of this ability takes more time.

Mounoud et al. (1985) examined the development of manual tracking in 5- to 9-year-old boys and concluded that 5-year-old children were able to produce a sinusoidal motion, but failed to create a global motor plan, including all characteristics of the target's motion. Often, a sequential pursuit strategy was observed at this age, in which short parts of the trajectory were planned and executed successively. The authors stated that the central representation of the target's motion became more and more elaborated with increasing age. They also found that low-speed targets were tracked successfully at a young age (above 5 years) but tracking high-speed targets improved until the age of 9 years. Zanone (1990) instructed 6- to 15-year-old children to manually track a visual target and found that the younger children relied mainly on the use of visual feedback to correct their movements, whereas the 15-year-olds adopted a feedforward strategy using a predictive model of the target's motion (see also Davidson & Wolpert, 2005).

To examine the ability of children and adolescents to quickly adjust the internal representation of the required movement of the pen tip, we designed a dynamic manual tracking task in which the target, which moved along a circular path, kept accelerating online when it was successfully tracked. The principal question was how the use of feedforward control developed throughout childhood and adolescence and whether tracking strategies changed with increasing age. For smooth *visual* pursuit of accelerating targets, it was recently shown that adults are able to use predictions of future target motion (Bennett & Barnes, 2006). Participants could scale their eye velocity appropriately to the expected target velocity after a short occlusion of the target but only when target velocity at reappearance was predictable (blocked presentations). To our knowledge, no studies have been performed in which the ability to *manually* track an accelerating target was examined in children and adolescents. Tracking an accelerating target requires the use of an ingenious predictive model of the target's motion, including not only the path along which the target moves and the velocity of the target but also its acceleration, to remain successful at higher target velocities (Magdaleno, Jex, & Johnson, 1970; Mounoud et al., 1983). It also requires a fast, continuous updating of this predictive model. Such a complex task is particularly useful to study the development of feedforward control.

It must be noted that at the start of a trial, the target moved at a low velocity, so that the task could be performed by using online visual feedback about position and velocity error to make corrections. However, with very fast moving targets, participants had to rely on feedforward control. It remained possible to perceive whether the cursor was inside or outside the target, but successful corrections based on that feedback information were not possible due to the visual–motor delay. The target was simply moving too fast. The correction would be made too late and the target would have decelerated as a result of bad tracking performance. The predictive model of the target's motion should include not only the future position of the target but also the future velocity and acceleration. On the basis of this model, the general motor plan was generated when the use of online feedback to generate corrections was impossible. Naturally, both visual and proprioceptive information about the movements that were made during task performance remained important sources regarding the target's trajectory, velocity, and acceleration. This information, gathered throughout the performance of the task, could be used to adjust the internal representation of the required movement of the pen tip to improve task performance in the rest of the trial and subsequent trials. The more appropriate this internal representation was, the better the task performance.

To test whether participants used online feedback during our tracking task, the number of submovements was determined by counting the number of velocity peaks per cm. In a study with monkeys (Roitman, Massaquoi, Takahashi, & Ebner, 2004), it was found that submovements during visually guided tracking reflected feedback-based corrective actions because they were highly correlated with specific error signals. Another strategy used to exploit feedback is the so-called step-and-hold strategy, in which movement velocity decreases to (close to) zero between submovements (Miall, Weir, & Stein, 1985, 1986; but see also Van der Meulen et al., 1990, for conflicting results). After a movement has been made to catch up with the target (a "step"), a stop ("hold") is made to determine what the next movement has to be. The participant is unable to pursue the target in a smooth way by predicting the movement of the target and anticipating to that. Mounoud et al. (1985) called it a sequential pursuit strategy, in which short parts of the trajectory are planned and executed successively. When the number of velocity peaks per cm and the number of stops are lower, a larger part of the tracking movement is made under feedforward control as fewer submovements are made. The movements are performed more smoothly.

We assumed that older children would be able to track the accelerating target at higher velocities than the younger ones because they will rely less on online feedback control and show a more optimal use of feedforward (or prospective) control based on a predictive model of the target's motion. This will result in higher maximum target velocities with increasing age, more circles drawn, less stops, and more fluent movements. We hypothesized that the rate of improvement would be highest at a younger age (Benguigui & Ripoll, 1998), leading to quadratic trends in the data (see also the Dependent Variables and Statistical Analysis section).

Method

Participants

Participants (N = 117, 62 girls, 55 boys, all Caucasian, mixed socioeconomic status [SES]) were recruited at two primary schools and a secondary school in Flanders, Belgium. First, the three schools that were willing to participate were visited to explain the study. Then, the parents of all children attending these schools were informed in writing about the study and they were asked for their permission. We aimed at including 10–15 boys and 10–15 girls of each of the five age groups we defined (6–7, 8–9, 10–11, 12–14, and 15–17 years). For each age group–gender combination, a random selection was made (if possible) from the group of children whose parents agreed with their participation. The ultimate number of participants in each subgroup was dependent on the number of informed consents from the parents and on the available testing time. All children had normal or corrected-to-normal vision. To measure their general motor skills (manual dexterity, ball skills, and equilibrium), all children were tested on the Movement Assessment Battery for Children (Henderson & Sugden, 1992; Smits-Engelsman, 1998). The percentile scores of the participants above 12 years of age were based on the norms of 11- to 12-year-olds. Of the 74 primary school children, 6 scored below the 15th percentile, and of the 43 secondary school children, 14 scored below the 15th percentile (11 of them scored especially poor at the equilibrium tasks). They were not excluded from participation. No definite motor control problems were identified as none of the children scored at or below the 5th percentile. Additional information about these age groups is provided in Table 1. This study was approved by the local Ethics Committee of Biomedical Research at the Katholieke Universiteit Leuven and performed in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki. The parents of all participants gave written informed consent. All children gave their assent.

Task and Procedure

The task, programmed in OASIS (De Jong, Hulstijn, Kosterman, & Smits-Engelsman, 1996) consisted of manually tracking a red dot (diameter 2.7 cm) presented on a 19-in. flat screen computer monitor that was vertically mounted in front of the participant. A digitizing tablet (WACOM UD-1218-RE), used to record the participant's response, was horizontally mounted on the table top, directly in front of the participant. The child moved the cursor, a small yellow dot (diameter 0.53 cm) that was also displayed on the monitor, by moving a wireless, electronic pen of normal appearance and weight and with an inkless pen point on a white sheet of paper (A3 format), positioned on the digitizer. The pen had to be held in the hand with which the child usually writes. The 2D position of the pen on the surface of the digitizer was

Table 1
Age Group Information

			Age		M-ABC percentile score	
Age group (years)	Boys (*N*)	Girls (*N*)	*M*	*SD*	*M*	*SD*
6–7	10	13	7 years 1 month	6 months	58	27
8–9	15	12	9 years 1 month	6 months	52	25
10–11	12	9	11 years 1 month	7 months	36	27
12–14	11	15	13 years 6 months	11 months	37	31
15–17	7	13	15 years 11 months	7 months	32	30

Note. M-ABC = Movement Assessment Battery for Children.

sampled at a frequency of 206 Hz and with an accuracy of 0.1 mm. At the start of each trial, the target velocity was 20°/s. Target velocity never dropped below this value throughout the task. When tracked successfully (i.e., the cursor being completely contained within the target for at least 75% of a 0.5 s time slice period), the target slowly accelerated with an angular velocity increase of 5%. Otherwise, it quickly decelerated (i.e., the angular velocity decreased with 23%) to allow reentry. Although acceleration and deceleration occurred in discrete steps, these steps were small, such that the target's motion was not perceived as being jerky. Participants were instructed to try to keep the yellow dot on the red target. To make the task more appealing, the target represented a villain and the cursor a policeman who had to keep the villain captured by remaining "on top of" him. Performance feedback (i.e., the number of circles drawn) was given after each trial. Two conditions were presented in which the red dot rotated along a circular path with a diameter of either 3 or 10 cm, clockwise for right-handed participants and counterclockwise for left-handed participants. It must be noted that the change in linear velocity across time was larger in the large circle condition than in the small circle condition, as it is the angular velocity that changed. A target moving at an angular motion of 20°/s covered a larger linear distance in a large circle as compared to a small one. Furthermore, the above-mentioned diameters of the target, cursor, and the circular trajectory reflected the sizes on the digitizing tablet. On the computer monitor, the diameters were all approximately twice as large. After one practice trial (duration 60 s) with large circular movements, two trials lasting 60 s each were performed within each condition. Half of the participants started with large and the other half with small circular movements. Data collection started when the distance between the centers of cursor and the target was less than 4.0 cm for the first time. Participants were allowed to rest between trials. The experiment lasted typically 10 min.

Dependent Variables and Statistical Analysis

The data were analyzed using Matlab and the OASIS software (De Jong et al., 1996). The 2D positional data of the pen were low-pass filtered using a zero-phase lag, second-order Butterworth filter with a cutoff frequency of 10 Hz and were subsequently differentiated to calculate movement velocity and acceleration (Matlab). The dependent variables were subdivided into measures that reflected tracking success and the extent to which feedback was used during tracking.

Measures of tracking success consisted of the number of circles completed during a trial and the maximum velocity of the target. These measures reflected to what extent a participant succeeded in unremittingly keeping the cursor within the target, even at higher target velocities. When tracking success was great, the target kept accelerating, resulting in more circles drawn and a higher target velocity. Additional measures were the median of the distance between the center of the target and the center of the cursor throughout a trial, the total amount of time that the cursor was on top of the target, and the median of the gain (i.e., the velocity of the cursor divided by the velocity of the target throughout a trial). These three measures also reflected how well a participant tracked the target. However, the velocity the target reached, which was an important indicator of the degree to which feedforward control was used, could not be inferred from these measures. To clarify this, note the following example. If someone could perfectly track the target, but only at lower velocities, the cursor would have left the target sometimes, namely whenever the velocity became too high, resulting in a decelerating target. The period that the cursor was outside of the target might be very short. The median of the distance between the centers could still be low under these circumstances, the duration within the target long, and the gain close to one.

To find out to which degree online feedback was used, we determined (a) the number of peaks per cm (i.e., normalized for the distance covered) in the velocity profile of the pen trace (in which a peak is defined as a point where the slope of the velocity curve changed sign), which corresponds to the number of submovements assumed to indicate corrective actions and (b) the number of times that the velocity of the pen was below 0.5 cm/s, reflecting the extent to which a feedback-based step-and-hold strategy was used.

Statistical analysis consisted of regression analyses and repeated measures analyses of variance (ANOVAs). Regression analyses were performed to reveal possible linear and quadratic trends across age groups. A linear relationship indicates a linear improvement of task performance with age. However, when the quadratic trend is also significant, this can point toward a later start of the improvement, a "leveling off" or stop of this improvement at a certain age, or even at a deterioration of task performance after an initial improvement or an improvement after an initial deterioration. We expected both linear and quadratic trends for our dependent variables. Children will evidently improve with age, but the improvement will be largest at a younger age (see also Benguigui &

Ripoll, 1998). Repeated measures ANOVAs were performed to test the effects of the within-subjects factors movement condition (two levels: small and large circular movements) and trial number (two levels: first and second trial within a condition), the effect of the between-subjects factor age group (five levels: 6–7, 8–9, 10–11, 12–14, and 15–17 years), and the interactions between these factors. So-called repeated contrasts were performed to test differences between successive age groups. An alpha level of .05 was used for all statistical tests.

Results

In Figures 1 and 2, some examples of task performance are displayed for a 7-year-old and a 16-year-old boy. For both conditions (big and small circles), the older boy drew more circles than the younger boy, as can be seen in the top two panels of each figure (X and Y location), which implies a better tracking performance by the older boy. The distance between the centers of target and cursor remained below 1 cm during the larger part of the trial (third panels). Finally, in the lower panels, it can be seen that the maximum target velocity (black line) was higher, whereas the number of stops (i.e., pen velocity below 0.5 cm/s) was lower for the older boy.

The means and standard deviations of the various dependent variables across the five age groups are presented in Table 2.

Number of Circles Drawn

Both a linear trend, $R^2 = .47$, $F(1, 115) = 102.91$, $p < .001$, and a quadratic trend, $R^2 = .51$, $F(2, 114) = 58.59$, $p < .001$, were found across age groups for the number of circles drawn. As can be seen in Figure 3A, the number of circles increases up to a certain age after which it levels off. This finding was confirmed by the ANOVA, which showed a main effect of age, $F(4, 112) = 29.43$, $p < .001$. The subsequent repeated contrasts indicated that only the differences between the 6- to 7-year-olds and the 8- to 9-year-olds and between the 8- to 9-year-olds and the 10- to 11-year-olds were significant ($ps < .001$).

To determine the effects of circle diameter and trial number, the data were first corrected for the difference in circumference of the drawn circles (circumference = diameter × π; i.e., for the large and small circles, it was 10π and 3π, respectively), by multiplying the amount of drawn circles in the big circle condition by 3.33. We found a main effect of diameter, $F(1, 112) = 971.67$, $p < .001$ (small circle condition: 25.1 circles drawn; big circle condition: 44.9 circles drawn), but there was also a significant interaction between diameter and age group, $F(4, 112) = 13.70$, $p < .001$. When the increase in the number of circles drawn between the conditions with small and large circular movements was expressed as a percentage (an increase of 100% means a doubling), the mean increase changed with age. For Age Groups 1–5, the increases were 63.1%, 76.6%, 78.7%, 79.9%, and 85.3%, respectively. The repeated contrasts between successive age groups showed similar age effects as compared to the overall analyses (Table 2) in the large circles and the small circles condition. There was also an effect of trial number, $F(1, 112) = 6.09$, $p = .015$, and a Diameter × Trial Number interaction, $F(1, 112) = 4.23$, $p = .042$, indicating that there was only an increase in the number of circles drawn between the first and the second trial (from 44.2 to 45.7 circles) in the big circle condition.

Maximum Target Velocity

A linear trend, $R^2 = .29$, $F(1, 115) = 47.79$, $p < .001$, as well as a quadratic trend, $R^2 = .33$, $F(2, 114) = 27.56$, $p < .001$, were found for maximum target velocity. Maximum target velocity increased with age from 8.9 until 13.4 cm/s, $F(4, 112) = 13.94$, $p < .001$, but contrasts indicated that only the performance difference between the 6- to 7-year-olds and the 8- to 9-year-olds and between the 8- to 9-year-olds and the 10- to 11-year-olds was significant ($ps = .015$ and .003, respectively).

Participants reached higher maximum target velocities when large circular movements had to be drawn (14.2 cm/s), instead of small circular movements (9.2 cm/s), $F(1, 112) = 326.55$, $p < .001$. There was also an interaction between diameter and age group, $F(4, 112) = 2.67$, $p = .036$. Repeated contrasts between successive age groups, for the small and the large circular movements separately, resulted in p values similar to the overall analyses (see Table 2), with the exception of the difference between Age Groups 1 and 2 in the small movement condition. This difference just failed to reach significance ($p = .054$).

Median of the Distance Between Centers of Cursor and Target

Again, both a linear trend, $R^2 = .12$, $F(1, 115) = 15.65$, $p = .001$, and a quadratic trend, $R^2 = .23$, $F(2, 114) = 17.05$, $p < .001$, were found (Figure 3B). The results of the ANOVA showed a main effect of age, $F(4, 112) = 8.76$, $p < .001$. The median of the distance

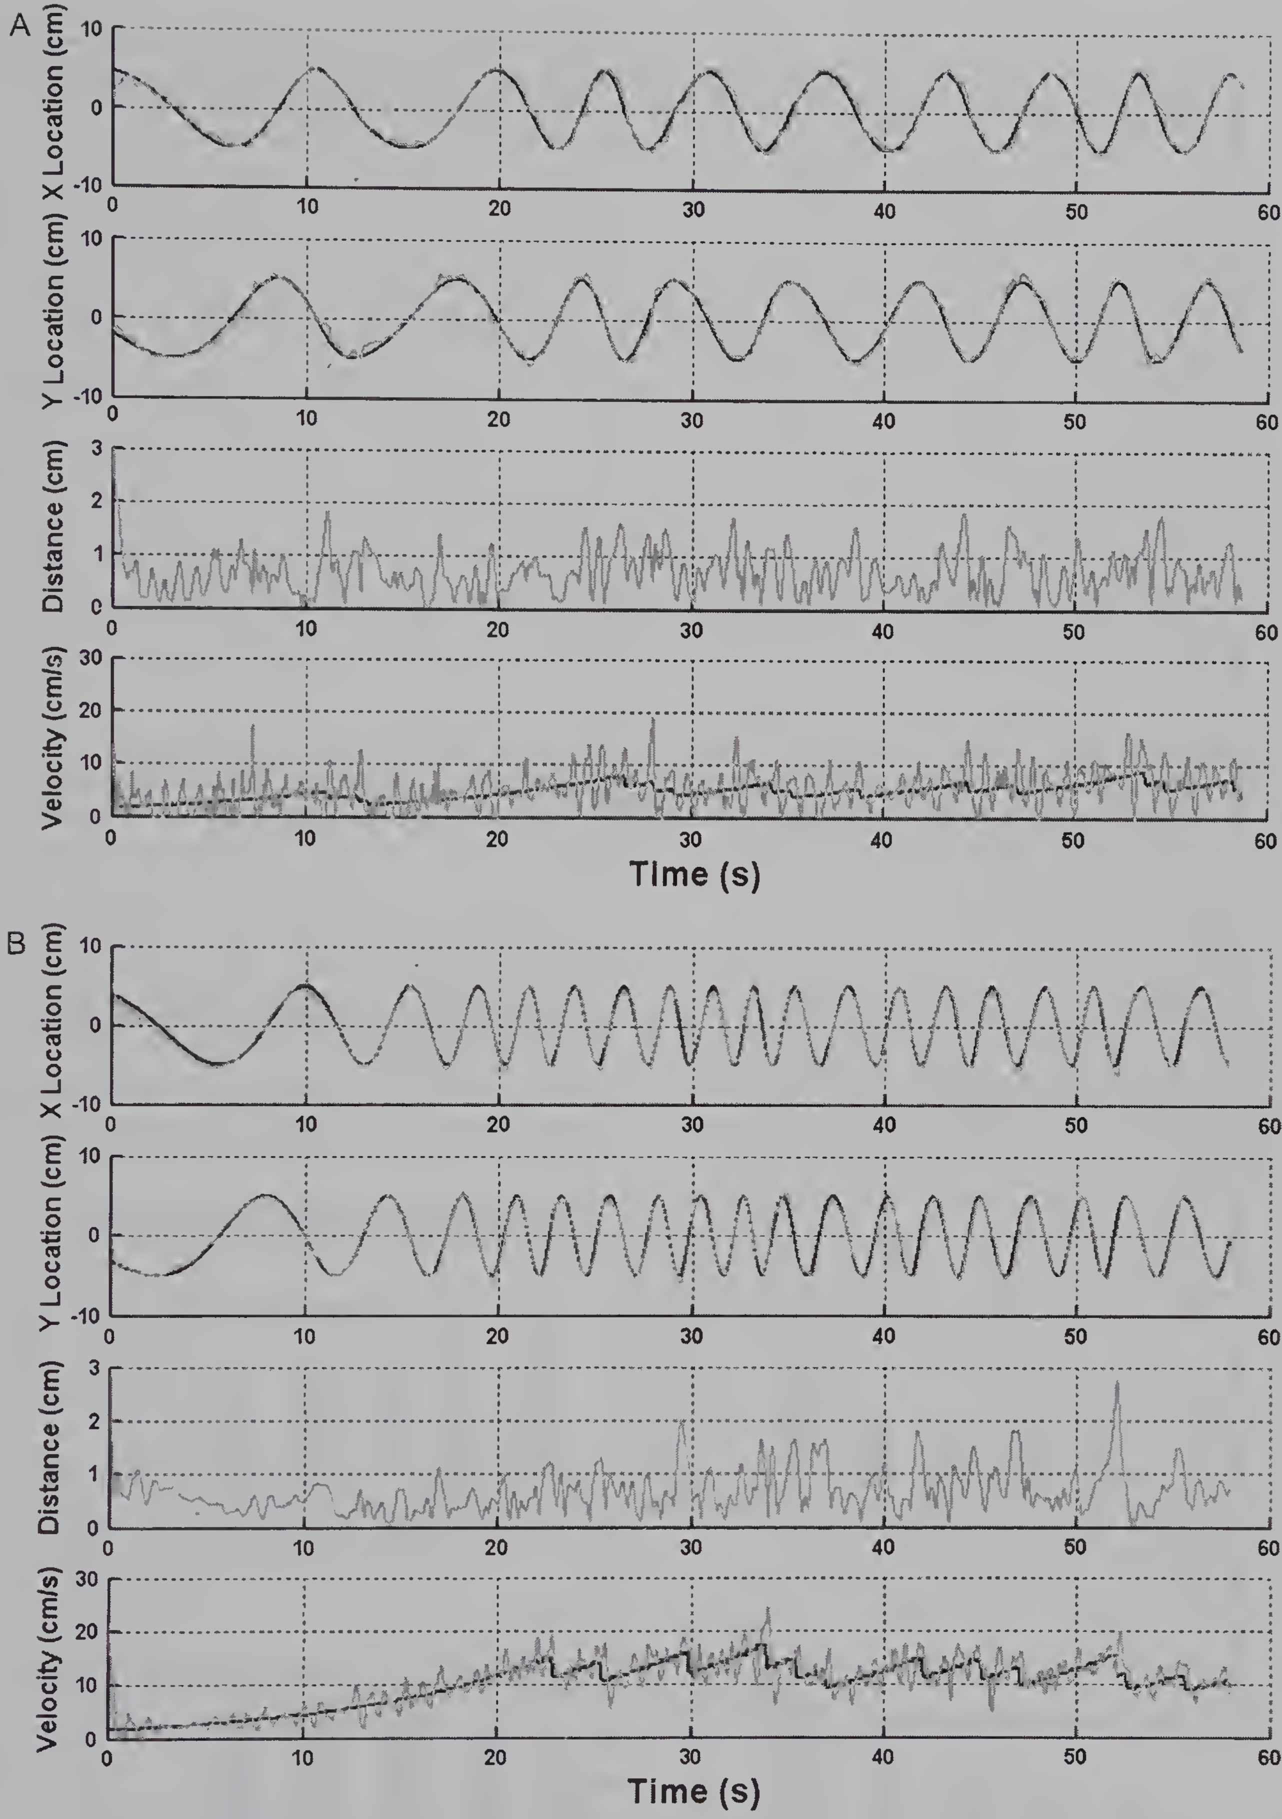

Figure 1. Typical examples of task performance in the *big* circles condition: (A) 7-year-old boy and (B) 16-year-old boy.
Note. In the top two panels of Figures 1A and 1B, the horizontal and vertical position of the centers of the target (black) and cursor (gray) throughout task performance are depicted. In the third panel, the distance between the centers of the target and the cursor is displayed, whereas in the last panel, the velocities of the target (black) and cursor (gray) are shown.

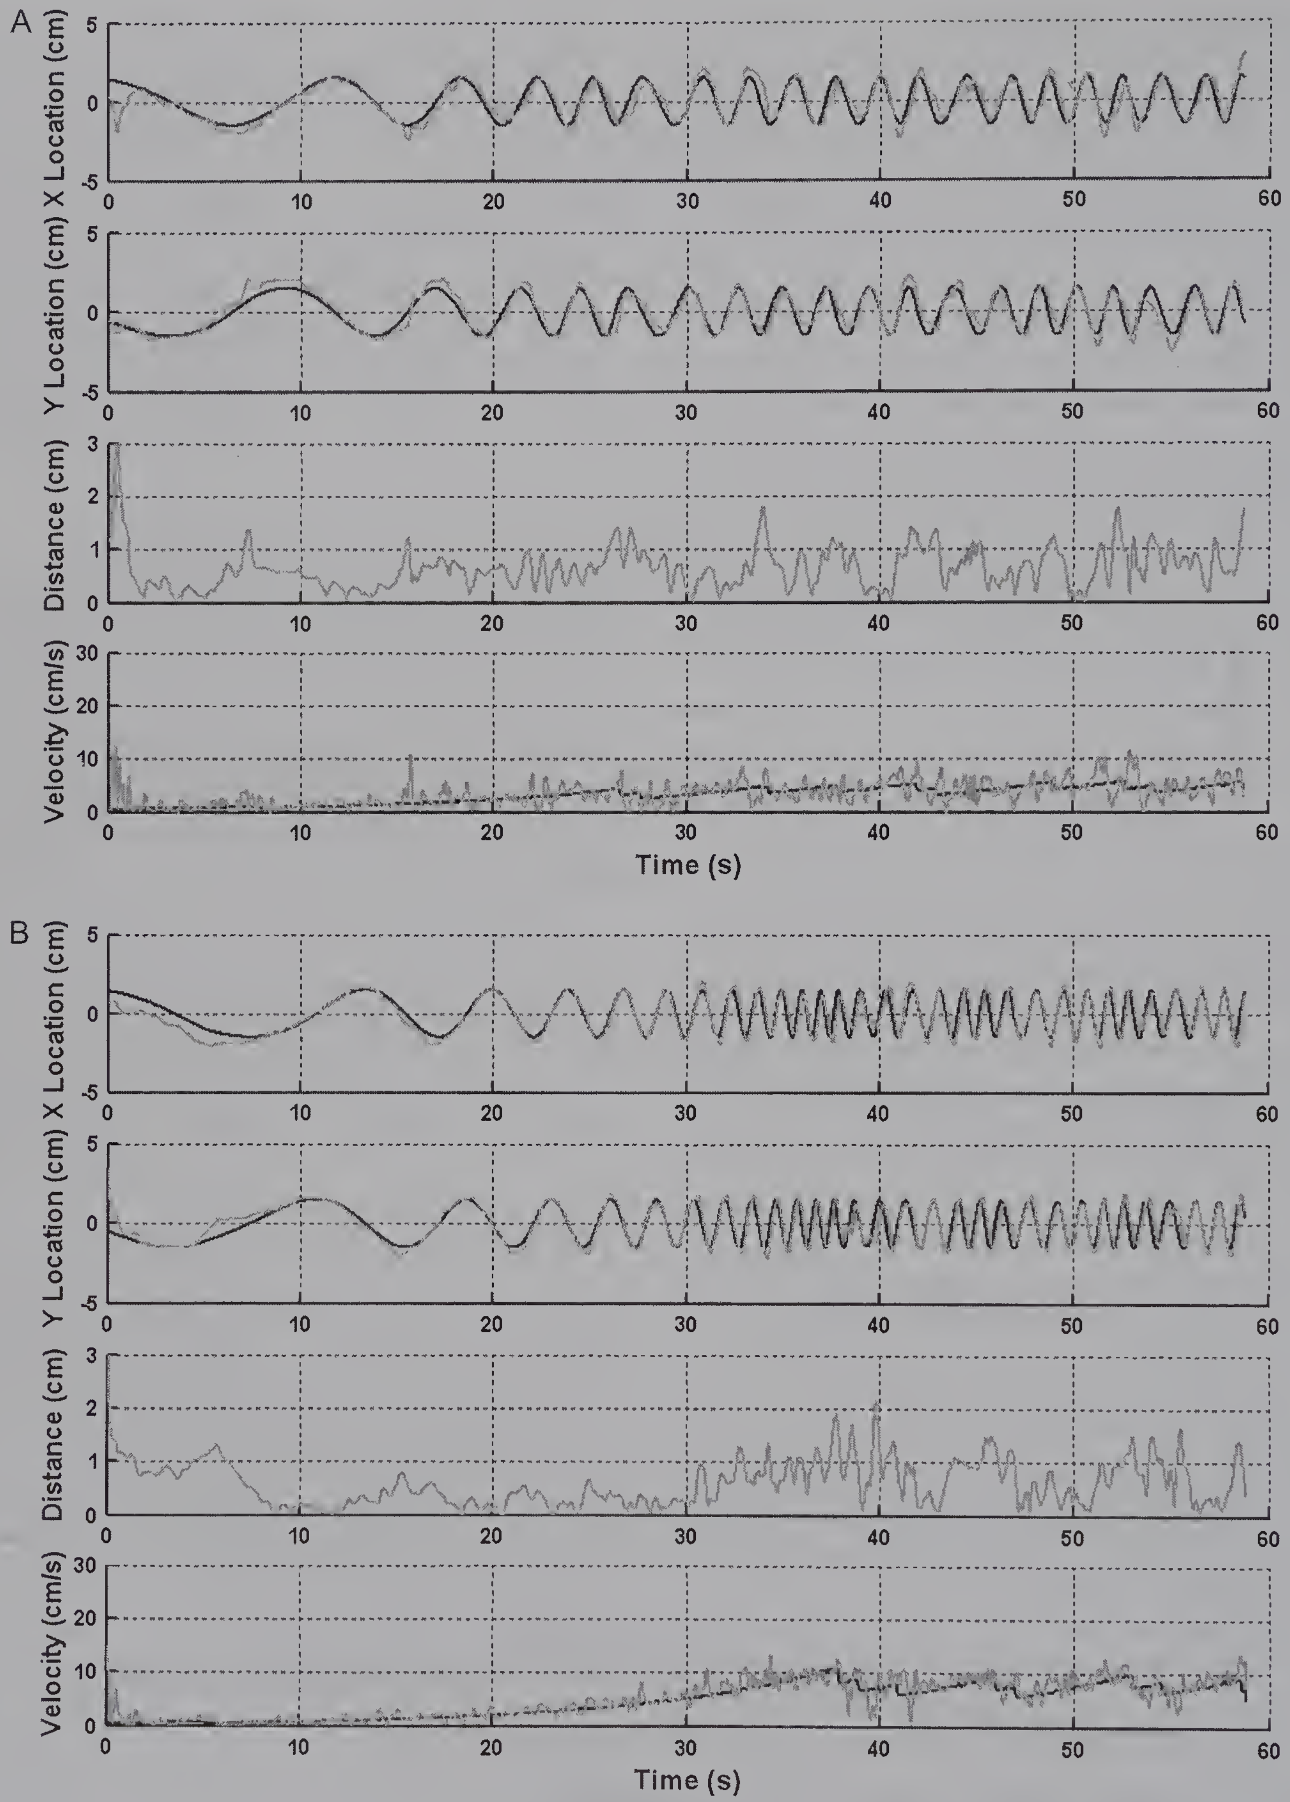

Figure 2. Typical examples of task performance in the *small* circles condition: (A) 7-year-old boy and (B) 16-year-old boy.
Note. In the top two panels of Figures 2A and 2B, the horizontal and vertical position of the centers of the target (black) and cursor (gray) throughout task performance are depicted. In the third panel, the distance between the centers of the target and the cursor is displayed, whereas in the last panel, the velocities of the target (black) and cursor (gray) are shown.

between the centers of target and cursor within a trial initially decreased with age but subsequently increased; it decreased between ages 6–7 and 8–9 ($p < .001$) and between ages 8–9 and 10–11 ($p = .019$), but it increased again between ages 10–11 and 12–14 ($p = .049$). No difference was found between the two oldest age groups. A main effect of diameter was found, $F(1, 112) = 92.89$, $p < .001$, showing that the median of the distance between the centers was larger for the large circular movements (0.61 cm) than for the small circular movements (0.55 cm). Besides the main effect of trial number, $F(1, 112) = 7.05$, $p = .009$, the Trial Number × Age Group interaction was also significant, $F(4, 112) = 3.19$, $p = .016$. The distance decreased with practice (from the first to the second trial), but only in age group 1 (from 0.62 cm to 0.60 cm; $p = .007$) and 3 (from 0.55 cm to 0.53 cm; $p = .001$).

Total Duration in Target

Regression analyses revealed both a linear trend, $R^2 = .26$, $F(1, 115) = 40.55$, $p < .001$, and a quadratic trend, $R^2 = .37$, $F(2, 114) = 33.02$, $p < .001$, showing that the amount of time the cursor was inside the

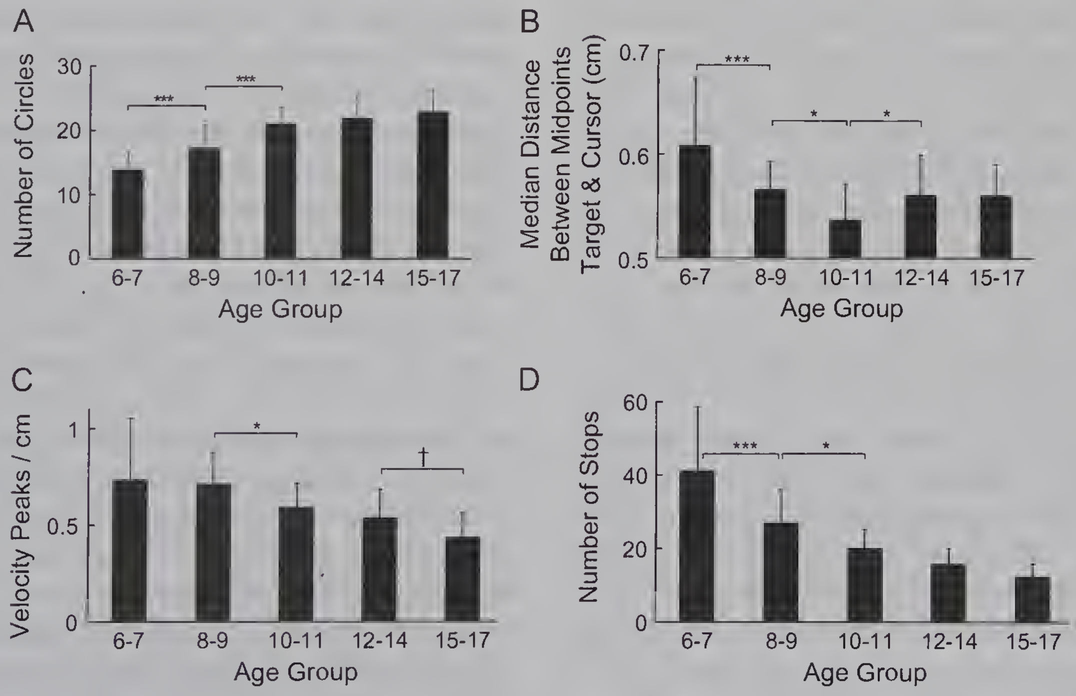

Figure 3. Effects of age group on (A) the number of circles drawn, (B) the distance between the center of the target and the center of the cursor in cm, (C) the number of velocity peaks per cm in the velocity profile of the pen, and (D) the number of stops (velocity < 0.5 cm/s).

$\dagger p < .10$. $^{*}p < .05$. $^{***}p < .001$.

target decreased in the youngest age groups, whereas it remained stable in the older age groups. Contrast analyses of the main effect of age, $F(4, 112) = 17.07$, $p < .001$, revealed that only the difference between the first two age groups was significant ($p < .001$), whereas the difference between ages 8–9 and 10–11 only reached marginal significance ($p = .062$). The cursor was in the target for a longer duration when the circles were small (51.2 s) as compared to large (48.9 s), $F(1, 112) = 298.86$, $p < .001$. Furthermore, the duration in the target was slightly longer in the second trial as compared to the first trial (49.8 vs. 50.2 s), $F(1, 112) = 12.59$, $p = .001$.

Median Gain

No effect of age group was found, neither with regression analyses nor with ANOVA. Averaged across all participants, the median gain was 0.998 ($SD = 0.061$).

Number of Velocity Peaks per Centimeter

As shown by the linear trend, $R^2 = .24$, $F(1, 115) = 36.89$, $p < .001$, and the quadratic trend, $R^2 = .25$, $F(2, 114) = 18.57$, $p < .001$, the number of velocity peaks per cm started to decrease at the age of 8–9 (Figure 3C). Contrast analyses of the main effect of age, $F(4, 112) = 9.42$, $p < .001$, showed a significant decrease in the amount of submovements in children ages 10–11 as compared to children ages 8–9 years ($p = .033$), whereas the decrease between ages 12–14 and 15–17 almost reached significance ($p = .071$). Movements were performed more smoothly in the large circle condition (0.34 velocity peaks per cm) than in the small circle condition (0.87 velocity peaks per cm), $F(1, 112) = 422.05$, $p < .001$.

Number of Stops

Both a linear trend, $R^2 = .48$, $F(1, 115) = 106.47$, $p < .001$, and a quadratic trend, $R^2 = .52$, $F(2, 114) = 62.79$, $p < .001$, were found across age groups, which indicates that the number of stops decreased with age but also that this decrease leveled off in the older age groups (Figure 3D). Contrast analyses of the main effect of age, $F(4, 112) = 31.47$, $p < .001$, revealed again that only the differences between the 6- to 7-year-olds and 8- to 9-year-olds and between the 8- to 9-year-olds and the 10- to 11-year-olds were significant ($p < .001$ and $p = .016$, respectively).

When the circular movements were large, participants stopped on average 12.7 times during task performance, whereas they stopped 34.2 times when small circular movements had to be drawn, $F(1, 112) = 652.51$, $p < .001$. The interaction between diameter of the circles and age group was, however, also significant, $F(4, 112) = 6.44$, $p < .001$; the effect of circle diameter was significant in all age groups, but the relative difference in the number of stops between large and small circle conditions (i.e., the increase expressed as a percentage of the number of stops in the large circle condition) increased with age. For Age Groups 1–5, the increases were 85.8%, 181.1%, 289.5%, 285.2%, and 267.5%, respectively). Age effects appeared to be similar in the large and the small circle condition. The repeated contrasts between successive age groups, for the small and the large circular movements separately, showed age effects similar to the overall analyses (Table 2), although an additional trend was found: In the small circles condition, the difference between the 10- to 11-year-olds and the 12- to 14-year-olds just failed to reach significance ($p = .052$).

Discussion

The aim of this study was to determine the development of feedforward control in children and adolescents during a dynamic manual tracking task and the ability to quickly adjust the predictive model of the target's motion. We examined the strategies children use when they have to flexibly adapt their movements to the changing velocities of the target while preserving accuracy (keeping the cursor within the target area). The number of circles and the maximum target velocity increased with age, whereas the number of velocity peaks and the number of stops decreased with age. We therefore conclude that a feedback-based strategy was gradually replaced by a more effective feedforward-based strategy to remain able to track high-speed targets.

All children were able to track the target, but the younger children (6- to 9-year-olds) could track the target only at lower velocities, whereas the older children and adolescents still tracked the target successfully at higher velocities, resulting in more completed circles. As can be concluded from the number of stops the participants made during tracking, the younger children made more use of a step-and-hold strategy (feedback based), which is only appropriate at lower velocities. With increasing age, the use of this strategy decreased (i.e., the number of stops decreased), whereas the use of a predictive model of the target's motion increased (e.g., higher maximum target velocities and less velocity peaks/cm). The linear decrease in the number of stops and the number of velocity peaks per cm continued until 15 – 17 years (see Table 2), although no longer significantly. Also note the finding that the number of velocity peaks per cm was similar in children ages 6 – 7 and 8 – 9 years but that the number of stops was significantly higher in the first age group. These developmental trends are hypothesized to be consistent with the unfolding of feedforward control processes.

Although speculative, we suggest three phases in the development of tracking control based on our results: (a) learning to stay on top of the target, (b) anticipating the movement of the target so that the target can be tracked at higher velocities, and (c) learning to rely less on online visual feedback, resulting in fewer submovements and increasingly higher possible target velocities. Our youngest participants ages 6 – 7 years were already able to stay on top of the target during the larger part of a 1-min trial. Moreover, the median distance between the centers of target and cursor and the median gain did not show large differences with those of the older age groups. However, the maximum target velocity increased up to ages 10 – 11, and decreases in the amount of submovements were found up to ages 15 – 17.

Various factors might have played a role in causing the age-related differences in task performance. In our view, the most important factor is the gradual improvement of feedforward processes over the course of development. The finding that the velocity of the target increased with age, up to a value at which the use of feedback was severely constrained—given the visual – motor delay—suggests that the part of the tracking movement that is made under feedforward control increased with age (see also the next paragraph). The younger children showed increased tracking difficulties at high target velocities, probably because they were unable to switch to feedforward control. The finding that the number of submovements decreased with age, as indicated by a decreasing number of velocity peaks per centimeter and stops, supports this. The movements became smoother with development. Feedforward processes can be subdivided in several separate processes that could have played a role during the performance of our tracking task: first, the use of predictive models of external object dynamics (i.e., the target's motion) and second, the use of predictive models of the dynamics of the arm (forward and inverse internal models; Davidson & Wolpert, 2005; Wolpert, Ghahramani, & Flanagan, 2001; Wolpert, Miall, & Kawato, 1998; for kinematic data that suggest the use of these forward and inverse internal models by children and the improvement of their quality with development, see Contreras-Vidal, 2006; Jansen-Osmann, Richter, Konczak, & Kalveram, 2002). Forward internal models predict the sensorimotor consequences of actions and the future state of the moving limb by using copies of motor commands (efference copies). This permits fast adjustments to the unfolding movement and reduces dependence on slower feedback control. Inverse internal models provide the motor command necessary to achieve some desired trajectory. Studies into the neural correlates of tracking behavior suggest that the cerebellum provides the predictive internal models necessary for the coordination between eye and hand movements during tracking (e.g., Miall & Jenkinson, 2005; Miall, Reckess, & Imamizu, 2001; Roitman, Pasalar, Johnson, & Ebner, 2005; Wolpert et al., 1998).

A second factor that might have played a role is the increased speed of information processing in older children enabling them to use feedback about position and velocity error at higher target velocities than younger children (Bourgeois & Hay, 2003; Wallace, Newell, & Wade, 1978; Wickens, 1974). Keele and Posner (1968) concluded that it takes about 200 ms to use visual feedback to correct aiming movements. Although Carlton (1981) found that the time between the presentation of visual error information and the initiation of a movement correction was only 135 ms, it must be noted that in our task, the target moved and its velocity changed online; accordingly, it would probably take more time to process visual feedback. Although it is merely speculation because it was not our aim to determine the visual – motor delay, we assume that this delay is at least 200 ms when performing our task.

We can approximately determine the maximum target velocity for the participant to be able to successfully use visual feedback to correct the tracking error. Imagine the situation in which the cursor is just inside the target and does not move while the target moves across this cursor. Then, the distance that the target travels between the first and the last moment that the cursor is completely inside the target area is 2.70 cm (the diameter of the target)—0.53 cm (the diameter of the cursor) = 2.17 cm (when we assume, to simplify matters, that the target moves on a straight line instead of in circles). The time interval during which the target covers this distance should be no longer than the visual – motor delay. When 2.17 cm is divided by the assumed visual – motor delay of 200 ms, it can be concluded that the maximum target velocity for the use of visual feedback to be possible was 10.9 cm/s, which approximately corresponded to the average maximum velocity the target reached in the age group of 8- to 9-year olds.

Hence, 6- to 9-year-old children might have used visual feedback to minimize the difference between the target and the cursor position. The average maximum target velocity in the 10- to 17-year-old participants varied between 12.8 and 13.4 cm/s. If they use only visual feedback to correct errors, the visual–motor delay should be around 165 ms, which might be too short a period given the complexity of our task. This might provide another indication that the older children use feedforward control when the target reaches velocities above 11 cm/s.

A third factor that might explain the age-related differences in task performance is the decreasing variability in motor output with increasing age (e.g., Schneiberg, Sveistrup, McFadyen, McKinley, & Levin, 2002) which simplifies the adequate prediction of the future position of the moving limb. As a result of this improved muscle coordination, reflected in more fluent movements, older children are also better able to make fast adjustments in movement velocity.

A fourth factor is the improvement of visual pursuit with age. In studies of oculomotor functioning, clear developmental trends were found, but the age at which visual tracking reaches adult levels is higher as compared to manual tracking. Ross, Radant, and Hommer (1993) found improvements in visual tracking of a target until the age of 15, but no older participants were tested. Katsanis, Iacono, and Harris (1998) found that during preadolescence (11–12 years of age), the oculomotor system is not working optimally, but by late adolescence (17–18 years of age), smooth pursuit eye tracking has reached adult levels of performance. When the visual tracking of a target improves, it is likely that manual tracking also improves because these movements are tightly coupled in a manual tracking task.

A final factor of importance is the ability to perceive acceleration. Unfortunately, to our knowledge, no studies have been done into developmental changes in children with regard to visual perception of acceleration. In a study with adults, Rosenbaum (1975) showed that acceleration can be perceived accurately, although this ability deteriorated with increasing acceleration. Also, results of Calderone and Kaiser (1989) suggest that adults are relatively sensitive to linear accelerations. Schmerler (1976) found that deceleration was easier to perceive than acceleration, but Calderone and Kaiser reported that this was dependent on the direction of motion. In addition, Schmerler, but also Gottsdanker, Frick, and Lockard (1961), reported that a gradual change in velocity (as in our study) is more difficult to detect than an abrupt change. If the ability to perceive acceleration is not yet developed in young children, then this might be a factor that influences the age-related differences in tracking performance that we found. However, it must be noted that besides the visual information about target acceleration, our participants also had proprioceptive information. They could have felt the acceleration of their moving hand while performing the tracking task. Von Hofsten and Rösblad (1988) showed that children between 5 and 12 years of age greatly improve on a pointing task in which they had to rely only on proprioceptive information.

We have considered the possibility that differences in fine motor control of the hands are a larger part of the explanation for the age-related differences that we found than differences in control strategies, especially for the small circle condition, as finger movements are more important in this condition than in the large circle condition. We examined the Age Group × Circle Size interactions that we found. If differences in fine motor control constituted a large part of the explanation for the age-related differences in our data, one would expect a larger difference between the youngest and the oldest children in the small circle condition than in the large circle condition. This did not appear to be the case (Table 3). The relative differences between the age groups were larger in the big circle condition, for the performance of which fine motor control of the hands was less necessary.

Table 3
Absolute and Relative Differences Between the Youngest and the Oldest Age Group for the Big and Small Circles Conditions Separately

		6–7 years	15–17 years	Absolute difference	Relative difference (%)
No. of circles	Big (corrected)	30.2	54.5	+24.3	+80
	Small	18.7	29.5	+10.8	+58
Maximum target velocity (cm/s)	Big	10.7	16.5	+5.8	+54
	Small	7.2	10.3	+3.1	+43
No. of stops	Big	28.7	5.3	−23.4	−82
	Small	53.4	19.5	−33.9	−63

Note. Differences were only calculated for the dependent variables for which age group × circle size interactions were found.

When we take stock of the complete set of results, we conclude that differences in control strategies are a more likely explanation than the differences in fine motor control of the hands.

Some other interesting results were found with respect to small versus large circular movements. Apparently, it was easier to track the target when it made the large as compared to the small circular movements. More circles were drawn and a higher maximum target velocity was reached. This might have been caused by the fact that the small circle has a much larger curvature in a smaller area. When we would have scaled the size of the target and, hence, the margin of error, for this difference in difficulty, the effects of circle diameter might have been absent or at least smaller, but the developmental trends would not have been different because all participants performed the task in the same two conditions. Furthermore, a difference in the amount of time available for the use of online feedback would have been introduced under these circumstances.

The tracking movement was also performed more smoothly (i.e., fewer submovements per centimeter) and fewer stops were made in the large circle condition. A possible explanation for these findings might be the difference in musculature used. When drawing large circles, the proximal joints (i.e., the elbow and shoulder) are primarily activated, whereas the distal joints (i.e., fingers and wrist) become more prominent when drawing smaller circles. The smoothness of the movement will benefit from the greater mass of the elbow and shoulder that will have a damping effect on the movement. In addition, the stronger muscles surrounding the more proximal joints generate less variable torques (Hamilton, Jones, & Wolpert, 2004). At the distal joints, the noise in the motor output is greater because they are acted upon by weaker muscles, leading to more variable movements. As a result of the higher inertia of the more proximal body segments, it is also more difficult to come to an almost complete stop during task performance when fast elbow and shoulder flexion–extension movements are performed as compared to flexion–extension movements of the fingers. These factors can also explain that the younger children show a relatively smaller increase in number of stops between the large and the small circle condition. Younger children have shorter fingers, so that they need to use their elbow and shoulder more when drawing small circles, whereas the older children have the possibility to use mainly their fingers and wrist to move the pencil.

Feedforward or prospective control is extremely important in daily life. Von Hofsten (1993) argued that "the development of action is basically a matter of acquiring prospective control" (p. 254) and that "actions constitute dynamic interactions between an organism and the outside world which, by necessity, have to be future-oriented" (p. 268). We have to make predictions about what is going to happen next in the outside world and adjust our movements accordingly. Although very young infants appear to be able to visually track a moving object and make inferences about the motion of objects that move behind occluders (Spelke et al., 1994), developmental changes can be observed into childhood when the task becomes more complex, as in our study. Participants not only had to visually track the target but also manually, and in addition, the target accelerated, resulting in a very complex predictive model of the target's motion required for successful tracking.

We assume that performance on our dynamic manual tracking task corresponds to performance of daily life motor activities in which prediction of object motion and anticipation of the person's movements to that object's motion is necessary. An example is catching or hitting fast approaching balls. Lefebvre and Reid (1998) showed that young children (ages 5–6 years) are worse in predicting ball flight as compared to older children (ages 7–12 years) at short viewing times. In a study of Benguigui and Ripoll (1998), tennis players and novices, 7, 10, 13, and 23 years of age, were asked to perform a task in which they had to predict the moment at which a moving object (with a constant velocity or a constant acceleration or a constant deceleration) would arrive on a target. Main improvements of timing accuracy were found between the ages of 7 and 10 years, which is comparable to the present findings. In addition, playing tennis ameliorates timing accuracy; the development of timing accuracy is accelerated.

To determine the quality of the internal representation of the required movement of the pen tip more directly, future studies might include a condition in which the target's visibility is intermittent, thereby forcing participants to rely on the predictive model of the target's motion. Velocity and acceleration of the target should not be dependent on tracking performance under these conditions. Otherwise task performance would become impossible. It might be an idea to first examine tracking performance with a continuously visible accelerating target so that participants can build the predictive model. In a subsequent trial, the target can disappear after some time so that reliance on the predictive model is required.

To examine the possibility that young children would have learned to perform the task after more practice, an experiment is required in which children perform the task many times. It might be that it just takes more time to build an adequate predictive model of the target's motion in younger children but that they can do it if allowed enough practice.

To summarize, we have provided evidence for the gradual maturation of feedforward control processes with increasing age. While growing up, children learn to exploit the advantages of feedforward control to be able to flexibly adapt their movements to the task demands. They gain experience in building a predictive model of both the target's motion and the dynamics of the arm, resulting in more efficient strategies.

Social and Cognitive Correlates of Children's Lying Behavior

Victoria Talwar
McGill University

Kang Lee
University of Toronto

The relation between children's lie-telling and their social and cognitive development was examined. Children (3–8 years) were told not to peek at a toy. Most children peeked and later lied about peeking. Children's subsequent verbal statements were not always consistent with their initial denial and leaked critical information revealing their deceit. Children's conceptual moral understanding of lies, executive functioning, and theory-of-mind understanding were also assessed. Children's initial false denials were related to their first-order belief understanding and their inhibitory control. Children's ability to maintain their lies was related to their second-order belief understanding. Children's lying was related to their moral evaluations. These findings suggest that social and cognitive factors may play an important role in children's lie-telling abilities.

Lying involves a speaker making a false statement with the intention to deceive the recipient (Bok, 1978; Chrisholm & Freehan, 1977; Coleman & Kay, 1981; Lee, 2000). Lie-telling behavior in children has received increased attention in recent years by developmental psychologists for both its theoretical implications in understanding children's social-cognitive development (e.g., Chandler, Fritz, & Hala, 1989; Leekam, 1993; Peskin, 1992; Polak & Harris, 1999; Sodian, 1991) and its practical applications in legal, clinical, and educational settings (e.g., Chagoya & Schkolne, 1986; Goodman et al., 2006; Lyon, 2000; Stouthamer-Loeber, 1986; Strichartz & Burton, 1990; Talwar, Lee, Bala, & Lindsay, 2002, 2004). The majority of existing research on children and lying has examined children's understanding and moral evaluation of lies (e.g., Bussey, 1992, 1999; Lee, Cameron, Xu, Fu, & Board, 1997; Lee & Ross, 1997; Siegal & Peterson, 1996, 1998; for a review, see Lee, 2000). These studies have shown that children show rudimentary conceptual and moral understanding of lying around 3 years of age but take more than a decade to reach maturity (e.g., being able to consider intention when categorizing a statement as a lie and evaluate its moral values). Only a limited number of studies have investigated children's actual lie-telling behavior, most of which have involved preschool children (e.g., Chandler et al., 1989; Lewis, Stanger, & Sullivan, 1989; Peskin, 1992; Polak & Harris, 1999; Talwar & Lee, 2002a, 2002b; Talwar, Murphy, & Lee, 2007; Talwar et al., 2002, 2004). Overall, these studies have found that lie-telling behavior emerges in the preschool years and that young children are able to deceive others early in life.

Children's Lie-Telling Behavior

The most frequently used method to study lying in children (e.g., Lewis et al., 1989; Polak & Harris, 1999; Talwar & Lee, 2002a; Talwar, Gordon, & Lee, 2007) is the temptation resistance paradigm pioneered by Sears, Rau, and Alpert (1965). In this paradigm, children are typically told explicitly by a researcher not to peek at or play with a toy when left alone. Due to children's curiosity and difficulty to resist temptation (hence, the name of the paradigm), most children tend to disobey the researcher's instruction. Upon returning, the researcher asks children whether they have peeked at or played with the toy. Thus, the temptation resistance paradigm creates a situation where children who have transgressed by disobeying an adults' instruction can make a decision either to lie or to tell the truth about their transgression. The advantage of this paradigm is that it elicits spontaneous lies from children (i.e., children are not instructed to lie) to conceal a transgression. More importantly, it mimics the naturalistic conditions in which children tend to lie (DePaulo & Jordan, 1982; Newton, Reddy, & Bull, 2000; Wilson, Smith, & Ross, 2003).

Observational studies (e.g., Newton et al., 2000; Wilson et al., 2003) have found that the most common and earliest lies children tell tend to conceal misdeeds where they have done something they were not supposed to do. Interestingly, despite the early and common occurrence of these types of lies, children of all ages and adults view them very negatively. For instance, Bussey (1992, 1999) found that children as young as 4 years of age rated lies about misdeeds as being very bad and that the liar would feel guilty for telling such a lie. Furthermore, they rated this type of lie more negatively than other types of lies and even misdeeds themselves.

In a classic study, Lewis et al. (1989) experimentally investigated 3-year-olds' deception to conceal their transgression with the use of the temptation resistance paradigm. Lewis et al. found that of the 33 children tested, 29 peeked and 38% lied about peeking at the toy. Lewis et al. concluded that children as young as 3 years of age are capable of verbally deceiving others. This result was replicated by Talwar and Lee (2002a) who showed that 36% of 3-year-olds lied about their peeking. They also found that unlike the 3-year-olds, the majority of the children between 4 and 7 years of age lied. Polak and Harris (1999) further modified Lewis et al.'s paradigm. They used a permissive condition where children were allowed to play with a toy and a prohibition condition where children were instructed not to touch the toy. Similar results were obtained with the majority of 3- and 5-year-olds lying in the prohibition condition, whereas all children in the permissive condition admitted to their touching the toy. Thus, Polak and Harris concluded that children's denials about their transgression reflected their deliberate attempt to mislead rather than forgetting. These results, along with the results of related research (Chandler et al., 1989; Lewis et al., 1989; Peskin, 1992; Talwar & Lee, 2002a), suggest that young children are able to engage in intentional verbal deceptive acts when given the opportunity.

Children's Ability to Lie Successfully

While children begin to tell lies from the preschool years, their abilities to lie successfully appear to develop well into middle childhood. To be successful in deceiving an intended dupe, a lie-teller must be able to not only produce a false statement but also ensure consistency between their initial lie with subsequent statements. Any inconsistencies in one's statements may lead to the detection of one's lies. The ability to maintain consistency between statements during deception is referred to as semantic leakage control in the literature (Talwar & Lee, 2002a). Talwar and Lee (2002a) found that when younger children were asked about the identity of the toy, even though children said they had not peeked at the toy, they often failed to feign ignorance and blurted out the identity of the toy. Talwar and Lee (2002a) showed transcripts of the children's exchange with the experimenter to university students who could easily detect children's lies. However, a developmental trend in children's ability at semantic leakage control was found. Whereas the majority of the children between 3 and 5 years blurted out the name of the toy that they denied having peeked at and thus implicated themselves as having transgressed, about half of the 6- and 7-year-olds feigned ignorance of the toy's identity. As a result, those children who feigned ignorance were not distinguishable from children who did not peek, and they were not detected by adults. This finding suggests that with age children become increasingly capable of maintaining consistency in their subsequent statements when lying.

Social and Cognitive Factors

It has been speculated that younger children may lack the cognitive abilities to be convincing lie-tellers (Talwar & Lee, 2002a), which may account for the developmental differences found in children's lie-telling behavior at different ages. However, there has been very little research on the exact social and cognitive factors that may play a role in children's ability to lie successfully. The limited existing research appears to suggest that children's theory-of-mind understanding, executive functioning, and their conceptual and moral understanding of lies may be related to their lie-telling abilities.

Theory-of-mind understanding. There exist two hypotheses regarding the relationship between theory-of-mind understanding and lie-telling. The first hypothesis suggests a relationship between children's lie-telling and their first-order belief understanding (Chandler et al., 1989; Polak & Harris, 1999), herein referred to as ToM_1 Hypothesis. The basis for this hypothesis is that telling a lie successfully requires deliberately creating a false belief in the mind of another. Acts of deception such as lying have been identified as early indicators of a child's understanding of belief and false belief (Chandler et al., 1989; Peskin, 1992; Ruffman, Olson, Ash, & Keenan, 1993; Sodian, 1991). Chandler et al. (1989) found that children as young as 3 years of age would intentionally create a false belief in another by withholding genuine information or planting false information. This conclusion remains controversial (Sodian, 1991;

Sodian, Taylor, Harris, & Perner, 1991). Further evidence of a relation between children's lying and theory-of-mind understanding comes from Polak and Harris (1999) who found that 3- and 5-year-olds' false belief understanding was related to their false denials about having played with a toy. However, their false belief understanding was not related to the lie-tellers' feigning ignorance in follow-up questions (i.e., failing to conceal their transgression and thus revealing the fact that their initial denial was false).

The second hypothesis posits that there is a relationship between children's abilities to maintain their lies and their second-order belief understanding (herein referred to the ToM_2 Hypothesis). Previous research has shown that second-order mental state understanding (e.g., Peter knows that Sally thinks it is raining) begins to emerge only around 6 years of age and undergoes steady development well into adolescence (Sullivan, Zaitchik, & Tager-Flusberg, 1994; Wimmer & Perner, 1983). Further, Banerjee and Yuill (1999) found that children who passed second-order belief tests were more likely to suggest story protagonists make false claims so as to present themselves in a positive light to others. Based on this evidence, Polak and Harris (1999) and Talwar and Lee (2002a) hypothesized, in the context of the aforementioned temptation resistance paradigm, that older children would be more likely to feign ignorance in follow-up questions and their successful deception would be linked to their performance on second-order belief tasks. They suggested that children's false denials of peeking only require the child to represent a belief that is different from the true state of affairs. Therefore, to falsely deny peeking requires only a first-order false belief understanding. However, to sustain the lie that one had not peeked, when asked the identity of the object they were told not to peek at, children had to infer what belief they ought to have, given the initial denial. Thus, Polak and Harris predicted that older children would be more likely to feign ignorance in follow-up questions than younger children and that success in doing so would be linked to performance on second-order false belief tasks. Indirect support for the ToM_2 Hypothesis comes from the findings of Talwar and Lee (2002a) demonstrating that 6- and 7-year-olds (who are known to have better second-order false belief understanding) were better at maintaining their lies than younger children. Recently, Talwar, Gordon, et al. (2007) provided direct support for the ToM_2 Hypothesis. They showed that feigning ignorance after having peeked at a toy was indeed significantly related to second-order belief scores among children between 7 and 11 years of age.

Thus, although initial false denials may be related to children's first-order belief understanding (ToM_1 Hypothesis), maintaining a lie in follow-up questions may be related to a child's ability to represent another's beliefs and what the other will infer from any knowledge revealed by the child (ToM_2 Hypothesis; Polak & Harris, 1999; Talwar, Gordon et al., 2007; Talwar & Lee, 2002a). However, these hypotheses have not been concurrently examined. Only one study has directly examined the ToM_1 Hypothesis (Polak & Harris, 1999) with 3- and 5-year-old children, and only one study has examined the ToM_2 Hypothesis with children 7 years and older (Talwar, Gordon, et al., 2007). The development of children's lie-telling behavior between 3 and 8 years of age, when critical changes in theory-of-mind understanding occurs, has not been examined, nor has the relationship between both children's first- and second-order belief understanding and their actual lie-telling behavior. Thus, one of the objectives of the current study was to examine the relationship between first- and second-order belief understanding and lie-telling abilities in children between 3 and 8 years of age.

Executive functioning. Some evidence exists that children's lie-telling behavior also might be related to executive functioning. Executive functioning has been defined as a set of higher order psychological processes involved in goal-oriented behavior under conscious control (Zelazo & Muller, 2002). Executive functioning encompasses a collection of cognitive skills including self-regulation, inhibitory control, planning, attentional flexibility, and strategy employment (Welsh, Pennington, & Groisser, 1991; Zelazo, Carter, Reznick, & Frye, 1997). Executive functioning skills have been shown to emerge in late infancy and develop during the childhood years (Welsh & Pennington, 1988; Zelazo & Muller, 2002), a time when researchers have noted increases in lie-telling skill (e.g., Polak & Harris, 1999; Talwar & Lee, 2002a). In particular, it has been suggested that inhibitory control and working memory may be directly related to children's deception (Carlson & Moses, 2001; Carlson, Moses, & Hix, 1998). Inhibitory control is the ability to suppress interfering thought processes or actions (Carlson, Moses, & Breton, 2002), and working memory is a system for temporarily holding and processing information in the mind (Baddeley, 1986). When lying, children have to suppress the reporting of the transgression that they wish to conceal and represent and utter the false information that differs from reality (Carlson et al., 1998, 2002). Additionally, to maintain their lies, children must inhibit those thoughts and statements that are contrary to their lie and that would reveal their transgression, while maintaining in their memory the contents of their lie. Thus, to tell lies and to lie successfully, children must be able to hold conflicting alternatives in their mind (i.e., what they really did/thought and what they said they did/thought).

Only one study has examined the relation between children's executive functioning and deceptive behavior (Carlson et al., 1998). Carlson et al. (1998) found that preschool children who experienced difficulty with executive functioning tasks, especially those that require a high level of inhibitory control, demonstrated difficulties with physical deception (i.e., pointing). Although Carlson et al. did not explicitly examine lie-telling behavior, their results seem to suggest that children may also have difficulties with lying if they lack advanced executive functioning skills, particularly in terms of inhibitory control and working memory. However, no study has directly tested this hypothesis. The current study aims to address this gap in the literature by examining the relationship between executive functioning and children's lie-telling abilities.

Children's conceptual and moral understanding of lying and truth-telling. Research has demonstrated that a child's conceptual and moral understanding of lie- and truth-telling emerges early in the preschool years and develops rapidly throughout the school years (Bussey, 1992, 1999; Peterson, Peterson, & Seeto, 1983; Piaget, 1932/1965; Siegal & Peterson, 1998; Talwar et al., 2002; see Lee, 2000, for a review). As young as 3 years of age, children already have a rudimentary concept of lies that are told for antisocial purposes and they evaluate such lies negatively. With increased age, children begin to differentiate antisocial lies from honest mistakes, guesses, exaggerations, and eventually sarcasm and irony. Children also gradually take into consideration the social context in which lies are told and the intention of the lie-teller when evaluating lies. Overall, by early adolescence, children's conceptual and moral understanding of lying and truth-telling becomes comparable to adults.

However, there has been limited research to examine the relationship between children's conceptual and moral understanding and their actual lying behavior. Talwar et al. (2002) found no relationship between children's actual lie- and truth-telling behavior and their conceptual and moral understanding of lies. The majority of children who reported that lying to conceal a transgression was bad, could correctly identify such a lie, and recommended others to tell the truth. Nevertheless, most of them told lies to conceal their own transgressions. Another study by Talwar et al. (2004) found a significant but modest correlation between children's conceptual and moral understanding and their lie-telling behavior to conceal a parent's transgression. It should be noted that in both studies, children's conceptual and moral understanding was assessed via tasks commonly used by legal professionals in the court (Bala, Lee, Lindsay, & Talwar, 2001; Lyon, 2000; Talwar et al., 2004). These tasks are typically very brief and only assessed whether children had a minimal understanding of lying and truth-telling. As a result, there was low variability in children's scores that may have obscured a genuine relationship between children's developing conceptual and moral knowledge and their lie-telling behavior. One of the objectives of the current study was to address this issue by using a more comprehensive measure of children's conceptual and moral understanding of lie- and truth-telling.

In summary, there have been few studies that have examined social and cognitive factors contributing to the development of lying or truth-telling. Furthermore, the few studies that have examined the relationship between social and cognitive factors (e.g., theory of mind, executive functioning, children's conceptual and moral judgment) and lying have only examined one factor and none have examined the differential role of these factors on children's lie-telling behavior. The aims of the present research were thus to address these gaps in the literature and to provide an integrated and comprehensive picture of the relationship between children's lie-telling behavior and various social and cognitive factors.

In the current study, to assess their lying behavior, children between 3 and 8 years of age participated in a temptation resistance paradigm similar to that used in the previous studies (Lewis et al., 1989; Talwar & Lee, 2002a; Talwar et al., 2002). Children were told not to peek at a toy while the researcher left the room. Later, children were asked to promise to tell the truth, and then questioned whether they had peeked. Children's conceptual and moral understanding was assessed using stories where children were asked to identify if the protagonist lied or not and rate their statements as good or bad (Bussey, 1992, 1999; Peterson et al., 1983; Siegal & Peterson, 1998). Children also completed three tests of executive functioning (Gerstadt, Hong, & Diamond, 1994; Hala, Hug, & Henderson, 2003; Kochanska, Murray, Jacques, Koenig, & Vandegeest, 1996) and four belief tasks (Hogrefe, Wimmer, & Perner, 1986; Sullivan et al., 1994; Wimmer & Hartl, 1991; Wimmer & Perner, 1983).

Based on existing evidence, we expected that as age increased, children who peeked at the toy would be more likely not only to deny their transgression (initial lie) but also to conceal their transgression when asked about the identity of the toy (i.e., semantic leakage control). For example, they would feign ignorance about the fact that they knew the identity of the toy. Further, it was expected that children's first-order belief understanding would predict children's lie-telling in the temptation resistance paradigm (ToM_1 Hypothesis) and their second-order belief understanding would predict their semantic leakage control (ToM_2 Hypothesis). It was also expected that better inhibitory control and better working memory would be positively associated with children's semantic leakage control to conceal their transgression in their verbal statements after an initial lie. For example, children who can hold information longer in their working memory and who do not respond impulsively would be more likely to feign ignorance about the identity of the toy. Finally, we hypothesized that children who had high conceptual and moral understanding of lie- and truth-telling (e.g., knowing the difference between truth and lies and its moral negativity) would be less likely to lie in the temptation resistance paradigm.

Method

Participants

Children (N = 150; 80 boys) between 3 and 8 years of age participated in the study (M = 65 months, SD = 12.3, range = 36 to 102 months). There were 77 preschool children (31 girls; M = 49.9, SD = 8.4) and 73 early elementary children (39 girls; M = 85.4, SD = 10.3). Henceforth, the former age group will be referred to as the younger group and the latter the older group. The children were predominately Caucasians and from middle-income families in a medium sized North American city (population: 120,000).

Measures and Procedure

Lie-telling behavior. The present study used a modified version of the temptation resistance paradigm used in previous studies (Lewis et al., 1989; Talwar & Lee, 2002a; Talwar et al., 2002) to examine children's lying behavior. After obtaining parental consent, each child was brought into a room with a researcher. In this room, each child and the researcher played a guessing game. Children were instructed to turn around in their chair so their back was to the researcher while the researcher played a sound from a toy. They were instructed not to break the rule by turning around in their chair to peek at the toy during the game. They could only look when the experimenter said so. Upon hearing the toy sound, the child was asked to guess what the toy was. All the toys were familiar to the children from television programs and stories (e.g., Buzz Light Year, Godzilla, Elmo), and all had familiar accompanying sounds that were clues to their identity. Throughout the game, children were repeatedly told of the no peeking rule. After the child correctly guessed the identity of two toys, the researcher was called out of the room. The researcher told the child she had to leave for a minute and that the third final toy would be left on the table with the sound playing. The third toy was a Barney doll and the sound that accompanied it was unrelated to the doll and came from a greeting card. Thus, the child could not guess correctly the identity of the toy based upon the sound that he/she heard. Prior to the researcher leaving the room, the child was told not to turn around and peek at the toy while the researcher was out of the room. The researcher then left the room for 1 min. A hidden video camera recorded the child's behavior while the researcher was absent. When the researcher, who was unaware of whether the child had peeked, returned to the room they told the child not to turn around and then covered the toy with a sheet. Once the toy was covered, the child was instructed to turn around in their chair. The researcher asked the child to promise to tell the truth. This procedure was adapted from Talwar et al. (2002). Asking children to promise to tell the truth was a major modification of the typical procedure because existing studies showed that without asking children to promise to tell the truth, the majority of children would lie (e.g., Lewis et al., 1989; Polak & Harris, 1999; Talwar & Lee, 2002a; Talwar et al., 2002). This would result in low variability in lying behavior leading to difficulty in revealing any potential relations between lying and social and cognitive factors. However, when children were asked to promise to tell the truth, close to 50% of the children would tell the truth (Talwar et al., 2002), making such a procedure ideal for examining the relations between lying and social and cognitive factors.

The child was then asked the critical question "When I was gone, did you peek at the toy?" and the follow-up question "Who do you think the toy is?" Children who gave a correct answer (Barney) were asked "How did you know who the toy was?"

Social and cognitive factors. Children returned on a second visit to complete three sets of social and cognitive tasks: conceptual and moral judgment tasks, theory-of-mind tasks, and executive functioning tasks. The order of the tasks was counterbalanced and each child was randomly assigned to one of the three different orders. The whole session lasted on average about 30 min with two short breaks given between tasks.

Concept and moral judgment tasks. To test children's conceptual and moral understanding of lie- and truth-telling, nine short stories were used. These stories involved various situations in which a character may have lied to conceal a transgression, told the truth about it, lied for a friend, made an honest mistake, inadvertently passed on a lie, told a white lie, played a trick, told an exaggeration, followed through on a promise, or failed to follow through on a promise. The stories were adapted from Bussey (1992, 1999), Siegal and Peterson (1998), Peterson et al. (1983), and Talwar and Lee (2002a). An example of one of the stories about lying to conceal a transgression is described below:

> Katy's teacher gave her candy for a special treat but told her not to eat it until after lunch. But, when Katy's teacher went away, she ate the candy before lunch. When her teacher came back and asked Katy if she had eaten the candy Katy said no

After each story was complete, the child was asked a concept classification question and an act evaluation question. The questions were modeled based on previous research that has examined children's conceptual and moral evaluations of lying and truth-telling (Bussey, 1992, 1999; Peterson et al., 1983; Siegal & Peterson, 1998; Talwar & Lee, 2002a; Wimmer, Gruber, & Perner, 1984). The concept classification question was, "Is what Katy in the story said a lie, the truth, or something else?" To score this component, each child was given 1 point for each concept question that he or she answered correctly across all stories, yielding a score out of 9. The act evaluation question was, "Is what Katy said, very very bad, very bad, bad, not good/not bad, good, very good, or very very good?" To help answer this question, children were instructed to indicate their answer using a 7-point Likert scale with stars indicating the positive ratings and Xs indicating the negative ratings. For example, if a child pointed to three stars, it indicated she thought the character's behavior was very very good. Two stars indicated very good, and one star indicated just good. This format was used in the same way for the Xs such that one X indicated bad, two Xs very bad, and three Xs very very bad. If a child believed the behavior to be not good and not bad they were instructed to point to the circle. Prior to giving the ratings, each child was trained on how to use the scale. This scale was adapted from previous studies (Bussey, 1992, 1999; Peterson et al., 1983), which found that preschoolers were able to successfully use this scale to evaluate lies. Children's ratings were then converted to scores for each moral question ranging between −3 to +3.

Theory-of-mind understanding. To test children's theory-of-mind understanding, five tasks were used. These five tasks were adapted from Hogrefe et al. (1986), Sullivan et al. (1994), Wimmer and Hartl (1991), and Wimmer and Perner (1983). These tasks included an unexpected contents first-order false belief task, two unexpected location first-order false belief stories, and two unexpected location second-order belief stories. The stories were acted out in puppet plays and shown to children on video. The order of the stories was counterbalanced between participants.

For the unexpected contents false belief task (Wimmer & Hartl, 1991), each child was presented with a box of Band-Aids in which some unexpected contents (i.e., crayons) were placed. The child was shown the Band-Aid box and asked what they thought was in the box. Following the child's answer, the box was opened to reveal a set of crayons. Upon showing the child that the actual contents, the box was closed. Then, the child was asked two questions about the contents of the box. First, the child was asked, "Before you looked inside, what did you think was in the box?" The child was then introduced to a puppet Max and asked, "What does Max think is in the box?" Each child was given 1 point for correctly answering each question. This procedure gave a possible score of 2.

The two unexpected location first-order belief stories were modeled after Wimmer and Perner (1983). One story involved Mark who puts his chocolate in one location before going out to play. His mother moves the chocolate to a second location while he is away. Each child was asked, "Where will Mark look for his chocolate bar?" The second story was the Sally-Ann story where Ann moves Sally's toy car while she is absent. Each child was asked, "Where does Sally think her toy car is?" For each story, the child received a score of 1 point for correctly attributing a false belief to the protagonist, for a total possible score of 2. Along with the contents false belief task, each child had a total "first-order belief score" out of 4.

The two second-order belief tasks were adapted from Hogrefe et al. (1986) and Sullivan et al. (1994). One story involved two children—John and Emma who encounter an ice cream man at the park. Emma goes home to get money for an ice cream. While she is gone, the ice cream man tells John he is going to the school to sell ice cream. On the way to the school, the ice cream man meets Emma and tells her he is going to the school. Throughout the puppet play, the child participant was asked control questions regarding the characters actions (e.g., "What did the ice cream man say to John?"). All children answered the control questions correctly. Each child was asked the following target questions: "Does John know that Emma knows where the ice cream man is now?" and "Where does John think Emma will go to buy ice cream?" Each child received a score of 1 point for correct answers to each question.

The second story involved two children, Mary and Simon, and their Grandpa. In the story, Grandpa gave the children a piece of chocolate to share. Simon wanted to keep the treat for himself so he hid it while Mary played outside. While Simon was busy hiding the chocolate, Mary was watching him through the window. During this puppet play, the child participant was asked several control questions (e.g., "Where has Simon put the chocolate?"). All children answered the control questions correctly. Each child was asked the following target questions: "Does Simon know that Mary knows where chocolate is now?" and "Where does Simon think Mary will look for the chocolate?" Each child received a score of 1 point for correct answers to each question. The total score for the two second-order belief stories was out of 4, which is henceforth referred to as the "second-order belief score."

Executive functioning. To test children's executive functioning, three tasks were used. One task (the whispers task) was a measure of inhibitory control (Kochanska et al., 1996), one (the Stroop task) was a measure of inhibitory control involving inhibition and working memory (Gerstadt et al., 1994; see Carlson & Moses, 2001, for discussion of task) and one (the six-box scramble task) was a measure of working memory (Hala et al., 2003). The order of the tasks was counterbalanced.

In the whispers task, the child was presented with 10 pictures picked out with the aid of their parent. These pictures consisted of story characters that children were familiar with and others that they were not. Child participants were told they would see a series of pictures, and after each picture, they had to tell the researcher who they thought was in the picture. The one rule that children were given for completing this task was that they were to whisper all their answers. To ensure that all the children understood how to whisper, they were asked to whisper their name and their age. It was recorded if the child responded with a whisper, a normal voice, a mixed voice, or a shout. Each child was given 3 points for correctly answering in a whisper, 2 points for answering in a normal voice, 1 point for answering in a mixed voice, and 0 points for answering in a shout. This yielded a possible score of 30.

For the Stroop task, each child was instructed that they would be playing a game of opposites. The child was shown a picture of a moon and asked what it was to ensure the child was familiar with the object. The child was then instructed to say "day or sun" each time the researcher showed them a picture of the moon. The child was then showed a picture of a sun. After ensuring familiarity with the object, the child was instructed to say "night or moon" each time the researcher showed them a picture of the sun. Two practice trials were performed to test the child's understanding of the rules. Following the practice trials, the child was shown 16 pictures, 8 of the sun and 8 of the moon. These pictures were randomly ordered to minimize predictability. Each child was given 1 point for answering correctly and 0 points for answering incorrectly with a total score out of 16.

The final executive functioning task was the six-box scramble task. Six boxes, each a different color, were placed on a plank in front of children. Each child was told that in each box the researcher had placed a sticker and that it was their job to find them. The child was told that he or she was only allowed to select one box at a time. After each selection, the boxes were scrambled and the child was allowed to choose again until he or she found all six stickers. The child was allowed to keep the stickers once he or she found them. To score this task, the number of trials needed for the children to find all stickers were added up and then subtracted from 15 (the maximum number of trials allowed).

Results

To examine children's lie-telling behavior and the relation to different social-cognitive measures, a series of analyses were conducted. First, descriptive statistical results regarding children's peeking and lie-telling behavior were obtained. Second, to examine differences between those children who lied and those who did not in their social and cognitive factor scores, analyses of variance (ANOVAs) were conducted. Finally, to examine what social and cognitive factors predicted children's behavior, hierarchical regression analyses were performed.

Peeking behavior. Overall, 82% of the children (123) peeked at the toy in the experimenter's absence, and on average, children peeked 11 s after the experimenter left the room (SD = 13.2), with half of the children peeking within 6 s. Regression analysis revealed no significant age and sex of child effects for peeking behavior (see below for details).

Initial lie. Of the 123 children who peeked, 79 (64%) children lied about their transgression, whereas 44 children (36%) confessed. Regression analysis revealed no significant age and sex of child effects (see below for details). All 27 children who refrained from peeking stated that they had not peeked.

Lie-teller's responses to the follow-up question (semantic leakage control). Of the 79 children who lied about peeking, 57 (72%) children gave the correct answer to the follow-up question, "What do you think the toy is?" whereas all 44 children who confessed to peeking gave the correct answer, $\chi^2(1, N = 123) = 7.18, p < .01$. Regression analysis revealed no significant age and sex of child effects (see below for details). All 27 children who refrained from peeking gave incorrect answers. Thus, it seems that few lie-tellers concealed their knowledge of the identity of the toy that they had peeked at. Most were unable to maintain their lie in answer to the follow-up question.

Children's answers to "How did you know what the toy was?" when they gave the correct answer were analyzed to examine further children's ability to maintain their initial lie. Children's answers were divided into two categories: plausible explanations that attempted to conceal their peeking (e.g., "I heard the music before and knew it was Barney," "My sister has the video and I hear that music on it," "I knew the song was Barney's") and explanations that revealed their peeking behavior or did not explain the correct answer (e.g., "I saw purple," "It looked like Barney," "I don't know") with 97% intercoder reliability. Of the 57 children who said the toy was Barney, 28 (49%) gave plausible answers, whereas 29 either said "I don't know" or implicated themselves (e.g., "I saw purple"). Regression analysis revealed a significant effect of age but no sex of child effect (see below for details). With increased age, children became better at maintaining their lies and giving plausible explanations that concealed their transgression. To illustrate this age effect, we dichotomized children's ages into a younger group (77 preschoolers: $M = 49.9$, $SD = 8.4$; 31 girls) and an older group (73 early elementary school children: $M = 85.4$, $SD = 10.3$; 39 girls): Seventy-seven percent of the older children gave plausible explanations, whereas only 29% of the younger children gave plausible explanations.

Univariate Analyses: Social and Cognitive Measures Related to Children's Lie-Telling Behavior

To further examine the differences between lie-tellers, confessors, and children who did not peek (nonpeekers) in terms of each social and cognitive factors (i.e., theory-of-mind understanding, executive function, and conceptual moral understanding), we conducted a 3 (type of child: liar, confessor, nonpeekers) × 2 (gender) × age (continuous variable) ANOVA on each social and cognitive factor. Age was treated as a continuous variable in these analyses to help increase the power of the analysis because only 1 *df* was used. The reason that individual ANOVAs were conducted on each social or cognitive measure was to ascertain whether our initial a priori hypothesis regarding each measure was correct.

Whispers task. There was a significant effect for age, $F(1, 149) = 16.36, p < .001, \eta^2 = .13$. To illustrate the significant age effect for this task as well as the other social-cognitive tasks (see below), we again dichotomized children's ages into two age groups: the younger children (the preschoolers) and the older children (the early elementary school children). As shown in Table 1, the older children's scores on the whispers task were significantly greater than the younger children's scores. No other factors were significant. There were no differences between lie-tellers, confessors, and nonpeekers.

Stroop task. There was a significant effect for age, $F(1, 149) = 41.28, p < .001, \eta^2 = .22$. Children's scores on the Stroop task increased with age (Table 1). There was also a significant effect for type of child, $F(2, 149) = 5.32, p < .01, \eta^2 = .07$. Bonferroni post hoc analyses revealed that confessors had significantly lower scores ($M = 10.68$, $SD = 4.47$) than lie-tellers ($M = 13.04$, $SD = 3.80$, $p < .01$) and nonpeekers ($M = 13.48$, $SD = 2.87$, $p < .05$). There were no significant differences between the two latter groups.

Six-box scramble task. There was a significant effect for age, $F(1, 149) = 7.27, p < .01, \eta^2 = .05$. Children's scores increased with age (Table 1). There was also

Table 1
Mean (SDs) Scores of Executive Functioning, Theory of Mind, and Conceptual Moral Knowledge by Age Group

	Younger children	Older children
Executive function		
Whispers	25.36 (6.14)	28.63 (2.27)
Stroop	11.09 (4.54)	13.83 (2.71)
Six-box scramble	7.58 (2.23)	8.45 (1.38)
Theory of mind		
First-order belief	1.88 (1.43)	3.40 (1.09)
Second-order belief	2.08 (0.99)	2.99 (0.54)
Conceptual moral judgments		
Conceptual knowledge	7.23 (2.03)	9.60 (2.50)
Moral evaluations		
Factuality	0.24 (1.15)	−0.25 (0.74)
Motivation	−0.15 (1.04)	0.16 (0.94)
Promise	0.11 (0.94)	−0.11 (1.05)

a significant effect for sex of child, $F(2, 149) = 7.27, p < .01, \eta^2 = .05$. Boys had lower scores on the six-box scramble ($M = 7.58, SD = 2.28$) than girls ($M = 8.51, SD = 1.22$). There were no differences between lie-tellers, confessors, and nonpeekers.

First-order belief. There was a significant effect for age, $F(1, 149) = 71.67, p < .001, \eta^2 = .38$. Children's first-order belief scores increased with age (Table 1). There was also a significant effect for type of child, $F(2, 149) = 4.79, p = .01, \eta^2 = .07$. Bonferroni post hoc analyses with lie-tellers as the reference group revealed that lie-tellers had significantly higher scores ($M = 3.04, SD = 1.28$) than confessors ($M = 1.93, SD = 1.50, p < .05$) or nonpeekers ($M = 2.52, SD = 1.60, p < .05$). Thus, it appears that ToM_1 Hypothesis was confirmed with children who initially lied having higher scores than those who confessed or did not peek.

Second-order belief. There was a significant effect for age, $F(1, 149) = 47.56, p < .001, \eta^2 = .25$. Children's second-order belief scores increased with age (Table 1). There were no other significant effects.

Children's conceptual knowledge of truthful and untruthful statements. There was a significant effect for age, $F(1, 149) = 91.89, p < .001, \eta^2 = .2$. Children's ability to correctly classify lies increased with age (Table 1). There were no other significant effects.

Children's moral judgments of truthful and untruthful statements. A factor analysis using the principal component method of extraction with varimax rotation was performed on children's ratings of the different stories (i.e., their answers to the act evaluation questions). This analysis yielded three factors that accounted for 54% of the variance (see Table 2). The first factor, labeled Factuality, contained evaluations of three stories (factor loadings above 0.4) including a trickery, white lie, and lying to conceal a transgression (eigenvalue = 2.29, 26% of the variance accounted for). The second factor, labeled Motivation, contained evaluations of four stories including lies for a friend, exaggerations, inadvertent lies, and mistakes (eigenvalue = 1.44, 16% of the variance accounted for). The third factor, labeled Promise, contained evaluations of two stories regarding promising and failure to keep a promise (eigenvalue = 1.15, 13% of the variance accounted for). For subsequent analyses, factor scores representing the three factors were derived.

Table 2
Factor Loading of Moral Judgments of Verbal Statements

	Factor		
Moral evaluation	Factuality	Motivation	Promise
Fail to follow through on a promise	.09	.15	−.87
Lie on behalf of a friend	.36	.46	−.03
White lie situation	.70	−.01	−.03
Lie about a transgression	.73	.27	−.02
Follow through on a promise	.15	.23	.78
Exaggeration	.30	.57	−.02
Trickery	.70	.12	.13
Inadvertently pass on a lie	.03	.63	.27
Mistake	−.10	.74	−.07

Three separate ANOVAs were performed for each of the three factor scores: Factuality, Motivation, and Promise with age as a continuous variable and type of child as a categorical variable. For the Factuality factor, there was a significant effect for age, $F(1, 149) = 4.92, p < .05, \eta^2 = .04$. Children's Factuality factor scores decreased with age (Table 1). There was also a significant effect for type of child, $F(2, 149) = 3.10, p < .05, \eta^2 = .04$. Bonferroni post hoc analyses revealed that confessors had higher Factuality factor scores ($M = 0.32, SD = 0.83$) than lie-tellers ($M = -0.17, SD = 1.05, p < .05$) or nonpeekers ($M = -0.02, SD = 0.99, p < .05$). For the Motivation factor, there was a significant effect for age, $F(1, 149) = 9.46, p < .01, \eta^2 = .06$. Children's Motivation factor scores increased with age (Table 1). There were no other significant effects. For the Promise factor, there was a significant effect for age, $F(1, 149) = 4.65, p < .05, \eta^2 = .03$. Children's Promise factor scores decreased with age (Table 1). There was also a significant effect for type of child, $F(2, 149) = 3.48, p < .05, \eta^2 = .05$. Bonferroni post hoc analyses revealed that nonpeekers had higher Promise factor scores ($M = .54, SD = 1.09$) than confessors ($M = -0.08, SD = .81, p < .05$) or lie-tellers ($M = -0.1, SD = 1.03, p < .05$).

Multivariate Analyses: Social and Cognitive Measures Relationship to Children's Behavior

Given the presence of several significant correlations among the independent variables shown in Table 3, a series of hierarchical regressions were conducted on children's behavior in the temptation resistance paradigm to examine whether social and cognitive factors were together or individually predictive of children's peeking (i.e., whether they peeked or did not peek), tendency to lie (i.e., whether they lied or told the truth), and ability to maintain their lies (i.e., whether they were able to feign ignorance after having told a lie). Based on previous research, it was expected that children's lie-telling behavior would be predicted by their theory of mind and executive function abilities.

Peeking behavior. A hierarchical logistic regression was conducted with children's peeking behavior

Table 3
Correlation Matrix Among Individual Social and Cognitive Variables

*$p \leq .05$. **$p \leq .01$.

(peeking or not peeking) as the predicted variable and child age (continuous variable) and sex entered in the first step and whispers task score, Stroop task score, six-box scramble task score, first-order and second-order belief score, concept classification score, and three factor scores were entered on a second step. For this and subsequent logistic regression analyses, the independent variables, because they were chosen for theoretical reasons (see Menard, 2002), were first entered as predictors. Additional predictors (i.e., interactions) were added individually to determine whether they would contribute significantly to the model. Significance was assessed by a Block chi-square test (also known as the chi-square difference test). In this test, the retention of each predictor in a model must increase the variability substantially in order to justify using a more complex model. The overall model was not significant, $\chi^2(11, N = 150) = 16.74$, *ns*.

Peek latency. In a hierarchical linear regression analysis with peekers' peek latency scores as the predicted variable and the same predictors described above, the overall model was not significant, $F(11, 111) = 1.07$, *ns*.

Initial lie (tendency to lie). A hierarchical logistic regression was conducted with children's initial tendency to lie or tell the truth as the predicted variable and child age and sex were entered in the first step and whispers task score, Stroop task score, six-box scramble task score, first-order and second-order belief score, concept classification score, and three factor scores were entered on a second step. The dependent variable was children's answers to the question "Did you peek?" (liars vs. confessors). The first model was not significant, $\chi^2(2, N = 123) = 1.51$, *ns*. The second model was significant, $\chi^2(11, N = 123) = 28.02$, $p < .01$. Children's Stroop scores were a significant predictor of lying ($\beta = 0.2$, Wald $= 8.5$, $p < .01$). Children who lied had higher Stroop task scores ($M = 13.04$, $SD = 3.8$) than children who confessed ($M = 10.68$, $SD = 4.47$). Children's first-order belief scores was a significant predictor of lying ($\beta = 0.88$, Wald $= 5.76$, $p < .05$). Children who lied had higher first-order belief scores ($M = 3.04$, $SD = 1.29$) than children who confessed ($M = 1.93$, $SD = 1.50$).

Lie-teller's responses to the follow-up question (semantic leakage control). A logistic regression analysis was conducted with children's responses to the follow-up question "Who do you think it is" (correct vs. incorrect) as the predicted variable. Child age and sex were entered in the first step, whispers task score, Stroop task score, six-box scramble task score, first-order and second-order belief score, concept classification score, and three moral judgment factor scores were entered on a second step (confessors were excluded from the analysis). The first model was not significant, $\chi^2(2, N = 79) = 1.63$, *ns*. The second the model was significant, $\chi^2(11, N = 79) = 23.80$, $p < .05$. Children's stroop scores were a significant predictor of lying ($\beta = -0.41$, Wald $= 3.9$, $p < .05$). Children who gave incorrect answers had higher Stroop task scores ($M = 14.86$, $SD = 1.13$) than children who gave the correct answer ($M = 12.33$, $SD = 4.23$).

A logistic regression was conducted on lie-tellers' explanations for giving a correct answer. Child age and sex were entered in the first step, and whispers task score, Stroop task score, six-box scramble task score, first-order and second-order belief score, concept classification score, and three moral judgment factor scores were entered on a second step (confessors were excluded from the analysis). The overall regression model was significant, $\chi^2(11, N = 57) = 23.42$, $p < .05$. In the first step, children's age significantly predicted children's explanations ($\beta = 0.79$, Wald $= 11.61$, $p < .001$). In the second step after age was partialed out, children's second-order belief scores were a significant predictor of children's explanations ($\beta = 1.47$, Wald $= 6.41$, $p < .05$). Children who gave plausible explanations that concealed their peeking had higher second-order belief scores ($M = 2.9$, $SD = 0.69$) than children who gave the correct answer ($M = 2.1$, $SD = 0.86$). Thus, present results supported the ToM$_2$ Hypothesis with children's second-order belief understanding predicting their ability to maintain their lies and provide plausible explanations that did not reveal their transgression.

Discussion

The current study investigated that children's lie-telling behavior and its relation to their theory of mind, executive functioning, and conceptual and moral knowledge of lie- and truth-telling was examined. Several major findings were obtained.

First, not only did most children peek at the forbidden toy, but also, when asked by an experimenter if they had peeked, 64% denied their transgression and thus lied. These findings are consistent with past research, which has found a strong tendency to lie in children under 7 years of age if they have transgressed (Lewis et al., 1989; Polak & Harris, 1999; Talwar & Lee, 2002a). However, unlike previous studies that did not ask children to promise to tell the truth and found that 3-year-olds were less likely to lie compared to older children, no such difference was found in the present study. Our findings are similar to Talwar et al. (2002) who found no age difference when children were asked to promise to tell the truth. Also like Talwar et al. (2002), we found a similar rate of lying and confessing with more children confessing after promising to tell the truth than that found in other studies when children were not asked to promise to tell the truth. Taking together the present and previous findings, it appears that by 3 years of age and after, the tendency to lie about one's own transgression remains strong throughout preschool and elementary school years. However, asking young children to promise to tell the truth can reduce their tendency to lie.

Second, it was hypothesized that older children would not only deny their transgression but also successfully control semantic leakage by concealing their lie in the follow-up questioning. Overall, lie-tellers did not feign ignorance in their response to the first follow-up question. They correctly named the identity of the toy. However, half of the children appeared to make attempts to conceal their transgression by providing seemingly plausible explanations about why they knew the identity of the toy and the tendency to give plausible explanations increased with age. Younger lie-tellers were more likely to correctly name the identity of the toy after claiming to not having peeked at the toy and then failed to give a plausible explanation for knowing the identity. Thus, it seems that as age increases, older children are more skilled at maintaining their lies in subsequent verbal statements after they have told an initial lie.

Third, it was hypothesized that children's lie-telling behavior would be related to their first- and second-order belief understanding. Specifically, it was expected that children who performed better on first-order belief tasks would be more likely to lie (ToM$_1$ Hypothesis) and children who performed better on second-order belief tasks would be better at maintaining semantic leakage control (ToM$_2$ Hypothesis). The present results support both hypotheses. Consistent with Polak and Harris (1999), children's performance on first-order belief tasks predicted the false denials of their peeking behavior. Thus, children's initial lies may reflect their ability to represent a false belief that is different from their belief about the true state of affairs.

Furthermore, those children who had higher second-order belief scores were also better at concealing their transgression in follow-up questions, thus supporting the ToM$_2$ Hypothesis (Polak & Harris, 1999; Talwar & Lee, 2002a). Our results are consistent with the findings of Talwar et al. (2007) that the second-order belief understanding of elementary school-aged children (7 years and older) is significantly related to their ability to maintain semantic leakage control. However, there exists a noteworthy difference between the present study and that of Talwar et al. (2007). In Talwar et al. (2007), children's second-order belief understanding was significantly related to their ability to feign ignorance. In contrast, in the present study, children's second-order belief understanding was not significantly related to their ability to feign ignorance but rather to their ability to provide plausible explanations to their correct naming of the forbidden toy. This difference, however, does not suggest inconsistencies between the two studies because the oldest children (7- and 8-year-olds) in the present study, like the youngest children (7- and 8-year-olds) in the Talwar et al. study, tended to blurt out the correct name of the forbidden toy. Thus, seeming inconsistencies in correlational results may reflect a developmental progression in children's ability at semantic leakage control, from being unable to control the leakage at all during the preschool years, to merely explaining away their leakage with plausible answers in the early elementary school years, to exercise greater leakage control by feigning ignorance altogether. It should be noted that future studies are needed to examine these differences and the relationship between children's theory-of-mind understanding and other types of lies (e.g., high-stakes lies where there are negative consequences to others, prosocial lies told to benefit others). It may be that when children must consider the consequences to others when lying, sharper developmental differences will be found in relation to their theory-of-mind understanding.

Nevertheless, these findings along with previous research begin to provide a developmental picture of children's lying to conceal their own transgression. Children's lying appears to progress through three levels (see also Polak & Harris, 1999; Talwar et al., 2007). First, children's "primary lies" begin around 2–3 years of age when children are first able to deliberately make factually untrue statements. Although it is still unclear whether such statements are a form of word play, wish fulfillment, or genuine deception (i.e., statements made with an intent to instill false belief into the mind of the recipient), children's first falsehoods are often linked to situations of rule violations and children's attempt to avoid incrimination, protect self-interests, or present themselves in a more positive light (Newton et al., 2000; Wilson et al., 2003). Given the fact that genuine lies told by children in later childhood tend to serve similar functions, such early falsehood may be a rudimentary form of intentional verbal deception. However, at this age, children's lies are still infrequent (Newton et al., 2000; Wilson et al., 2003) with approximately half of the 3-year-olds lying about their transgressions, whereas the remainder tend to be honest and confess their transgression when asked by adults (e.g., Lewis et al., 1989; Polak & Harris, 1999; Talwar & Lee, 2002a).

The second level, "secondary lies," reflects a significant shift that takes place between 3 and 4 years of age (Chandler et al., 1989; Peskin, 1992; Polak & Harris, 1999). At and after 4 years of age, the majority of children will readily tell a lie to conceal their own transgression. The results of the present study and previous studies show that children's acquisition of first-order belief understanding may play an important role in children's progression from the first to the second level. Perhaps also related to the development of first-order belief understanding, children are able to regulate successfully their nonverbal behaviors to appear honest (Talwar & Lee, 2002a). However, many children at the secondary level appear to have difficulty at semantic leakage control. Their subsequent statements following an initial false statement tend to be inconsistent with the initial lie and thus make their deception readily detected by naïve adults (Talwar & Lee, 2002a). The third level, "tertiary lies," emerges around 7–8 years of age. At this level, children become gradually more and more sophisticated at semantic leakage control. Children will tell a deliberate lie while ensuring that their subsequent statements do not contradict the initial lie and thus make their statements difficult to distinguish from statements made by a nonliar. As found in the present study, children's second-order belief understanding may play an important role in the transition from the secondary to the tertiary level. This is perhaps because such understanding "allows intentional social coordination to occur" (Perner, 1988, p. 272) such that children can reason about complex interactions between mental states involved in sustaining a lie and act appropriately.

Fourth, the present study found a significant relation between children's executive functioning and their lying behavior. Children with higher Stroop task scores were more likely to lie. When children were asked if they peeked, children had to suppress the reporting of the transgression that they wished to conceal and represent and utter the false information that differs from reality. The inhibitory control that is needed to tell such a lie may be the same executive functioning skills that are involved in performing the Stroop task. Our findings are generally in line with Carlson et al. (1998) who found that children who experienced difficulty with executive functioning tasks, especially those that require a high level of inhibitory control, demonstrated difficulties with deception tasks. The Stroop task also involves working memory (see Carlson & Moses, 2001). It is thus possible that working memory may also play a role in children's decision to lie. Telling a lie may require the dual ability to remember the rule being violated and inhibit reporting of the transgression that they wish to conceal. However, it should be noted that two other executive functioning tasks (one of inhibitory control and one of working memory) were not found to be related to lying. Thus, further investigation of the relations between lying and both inhibitory control and working memory is required to examine the differential impact of these abilities by using tasks where inhibitory control and working memory can be readily isolated. Nevertheless, the present findings suggest that the development of children's lie-telling abilities is not only related to children's theory-of-mind abilities but also to their executive functioning skills. This finding may not be surprising because research has consistently shown a significant relationship between children's theory-of-mind understanding and their executive functioning (e.g., Carlson et al. 2002; Hughes, 1998; Perner, Lang, & Kloo, 2002). Interestingly, dual executive demand tasks like the

Stroop task used in this study have been found to be more strongly predictive of theory-of-mind capabilities than working memory or inhibitory tasks alone (e.g., Carlson & Moses, 2001; Hala et al., 2003). Given this finding, it may be that the combination of inhibitory control and working memory may be crucial not only for ToM reasoning but also for lying, which requires children to put their theory-of-mind knowledge into action.

The fifth major finding of the present study is the lack of a significant relation between children conceptual understanding of lie- and truth-telling and children's actual behavior. Consistent with previous studies, in the current study, children's concept classification scores increased with age (Bussey, 1992, 1999; Lee, 2000; Peterson et al., 1983; Siegal & Peterson, 1998; Talwar et al., 2002). Although a much more comprehensive measure of children's conceptual knowledge was used in the present study, the findings were similar to the two other studies that have examined the relationship between children's conceptual understanding and their actual lying behavior (Talwar et al., 2002, 2004). Perhaps this is not surprising given that adults know what a lie is but still lie on a day-to-day basis (DePaulo & Kashy, 1998). Taken together, these findings suggest that children's ability to classify truth and lies does not prevent them from telling lies to conceal their transgressions. Future studies should examine if this is also true for children's lie-telling behavior in other situations such as lies told for prosocial reasons (e.g., white lies).

Similar to previous studies (e.g., Bussey, 1992, 1999; Piaget, 1932/1965; Siegal & Peterson, 1998), children's age was significantly related to their evaluations of the moral stories. When making moral judgments, younger children were more likely to attend to factors of factuality and promising than older children. However, they were less likely to take motivation into consideration when compared to older children. Thus, younger children paid more attention to the factuality of a statement and the adherence or violation of rules (e.g., promise keeping or breaking) to make their moral evaluations, whereas older children considered the character's intention to deceive itself to make their evaluations. These findings are in keeping with previous studies that have found that although children as young as 4 years of age can make basic distinctions between lies and truth, their moral understanding of lies develops over time with younger children being more influenced by factuality of statements and external factors, whereas older children are more influenced by intentions and internal factors (e.g., Bussey, 1992, 1999; Peterson et al., 1983; Piaget, 1932/1965). Therefore, to fully understand children's emerging understanding of lies, it is important to examine not only their classification abilities but also their evaluations of truthful and untruthful statements.

More importantly, the sixth major finding of the present study showed children's lying behavior to be related to their moral evaluations. These findings are different from previous studies (Talwar et al., 2002, 2004) that found no or limited relation between moral understanding and behavior, perhaps due to the fact that the current study used a more comprehensive measure of children's moral understanding. More specifically, the confessors had higher Factuality scores than lie-tellers. In other words, children who admitted their transgression were more likely to value truthfulness and give it higher ratings regardless of the situation. In contrast, children who chose to lie tended not to have stringent views about the need to be truthful. These results suggest that children who hold more relativist views about the moral implication of lying might be more inclined to tell lies, whereas those who held more stringent moral views about lying are more likely confess. Another noteworthy finding is that in comparison with the liars and confessors, nonpeekers gave the most positive ratings for stories where the protagonist kept a promise and the most negative ratings when the story protagonist failed to keep a promise. One possible explanation is that nonpeekers were the most concerned about rules and adherence to them. They might have taken the experimenter's instruction about not peeking at the forbidden toy more seriously than the lie-tellers and confessors, and this concern was strong enough to motivate them to resist the high-level temptation to peek in the current procedure. Thus, although children's ability to classify whether a statement was a lie was not related to their behavior, their perceptions of the acceptability of such statements were significantly related to their behavior.

A few caveats to our findings are warranted. First, the present study involved children' disobeying an adult's instruction and lying to them about their transgression. Although previous research suggests that this kind of lie is common among children told to parents and teachers and they also considered it to be a serious moral violation (Bussey, 1992, 1999; DePaulo & Jordan, 1982; Newton et al., 2000; Stouthamer-Loeber, 1986; Wilson et al., 2003), the violation itself is not severe and hence may be of low stake in nature. When the stakes are high or consequences of transgressions are more serious, children's behavior as well as its relation to moral judgment may change. Given the obvious ethical challenges of creating such situations, this type of lie has not yet been systematically examined. Nevertheless, research with adults suggests that in high-stakes situations, we are less likely to conform to our moral knowledge and standards and more likely to act out of self-oriented motivation (Batson & Thompson, 2001). Second, the present study was the first study to find a relation between children's moral understanding and their lie-telling behavior with the use of more extensive measures of children's moral understanding than those used in previous studies that failed to find a significant relation. Despite this methodological improvement, it is possible that a more refined assessment may yield an even stronger relationship. Furthermore, because we only used one behavioral measure, it is unclear whether children's moral understanding is also related to other types of lying such as white-lie-telling. Future research with multiple behavioral and moral understanding measures will provide necessary evidence to elucidate how children's behaviors are influenced by their moral knowledge about lying and honesty and vice versa.

In summary, current findings demonstrate that the majority of children between 3 and 8 years of age will lie to conceal their transgressions and their ability to maintain these lies increases with age. Children's ability at semantic leakage control increased not only with age but also with increased cognitive sophistication. Lie-telling behavior was related to both children's theory of mind and executive functioning abilities. Although children's deception is often considered to be problematic, the current study's results suggest that lying is associated positively with children's cognitive development in terms of their understanding of others' minds and executive functioning. The present study serves only as the first step in understanding possible contributing factors to the development of children's deception, focusing only on the contribution of three major social and cognitive factors to children's lie-telling behavior. Other factors that may influence children's deceptive abilities need to be examined in future studies. For instance, children's general intellectual ability, parenting styles, disciplinary styles, and cultural contexts may be also related to the development of lie-telling behavior (Achenbach & Edelbrock, 1981; Cole & Mitchell, 1998; Crossman & Lewis, 2006; Lee et al., 1997; Lewis, 1993; Stouthamer-Loeber & Loeber, 1986).

Moral Development in a Violent Society: Colombian Children's Judgments in the Context of Survival and Revenge

Roberto Posada and Cecilia Wainryb
University of Utah

Ninety-six Colombian children (mean age = 7.7 years) and adolescents (mean age = 14.6 years) made judgments about stealing and physical harm in the abstract and in the context of survival and revenge. All participants judged it wrong to steal or hurt others because of considerations with justice and welfare, and most also judged it wrong to engage in such actions even when they can aid in survival. Their judgments in the context of revenge were more mixed, with a sizable proportion endorsing stealing and hurting in that condition. Furthermore, the majority expected that people would steal and hurt others in most situations. Significant age differences were also found. The consequences of political violence for moral development are discussed.

As reported by the UN Office of the Special Representative of the Secretary General for Children and Armed Conflict, children in approximately 50 countries around the world currently grow up in the midst of armed conflict and its aftermath. In the past decade, 6 million children were injured due to war and 2 million were killed. Millions of children have been uprooted as a consequence of armed conflict and human rights violations, seeking safety abroad or within their own borders; indeed, well over half of the world's displaced people are children. Currently, it is estimated that there are 10 million children refugees worldwide; an additional 13 million children are internally displaced within their own countries (United Nations, 2006). In Colombia alone, the site of the present study, almost 2 million children have been forcibly displaced from their homes and towns during the past 15 years. Appalling and shocking in and of themselves, these figures also carry the disturbing implication that more and more of the world's children are being sucked into a bleak moral vacuum—a psychological space devoid of basic human rights and values. How might children's development be altered by the violence, lawlessness, and deprivation to which they are exposed?

Psychologists have long been concerned with the effects that long-term exposure to violent conditions has on children's psychological well-being. While much of this research has been conducted in violent communities within the United States (e.g., Buka, Stichick, Birdthistle, & Earls, 2001; Richters & Martinez, 1993), studies have also been conducted in countries at war, such as Israel and the occupied West Bank and Gaza, Lebanon, and South Africa (e.g., Barber, Schluterman, Denny, & McCouch, 2006; Macksoud & Aber, 1996; Punamäki, 1996; Straker, Mendelson, Moosa, & Tudin, 1996). Most research efforts in this regard have used a trauma model and measured the consequences of chronic exposure to violence in terms of mental health outcomes. Findings concerning children's specific patterns of symptoms have varied across studies as a function of the domains of adjustment targeted and the characteristics of the samples studied. In general, however, children's reactions associated with exposure to chronic violence have included anxiety, depression, psychosomatic disturbances, and other symptoms that have come to be associated with posttraumatic stress (Richters & Martinez, 1993).

Still, children may respond in complex ways that are not necessarily captured by the posttraumatic stress disorder (PTSD) diagnostic criteria, and the exclusive focus on psychiatric symptoms might be mistakenly taken to imply that children who do not receive a diagnosis are unaffected. Nonetheless, in comparison to the large volume of work documenting the clinical consequences of exposure to political violence, very little is known about the nonclinical impact that growing up in such conditions may have on children. Indeed, in their commentary to the Special Issue devoted to children growing up in the midst of political violence that appeared a decade ago in *Child Development*, Cairns

---

This article is based on the first author's master's thesis. The research was supported by two fellowships (2003–2004 and 2004–2005) from the Barbara and Norman Tanner Center for the Prevention of Violence.

and Dawes (1996) noted the scarcity of research on the significance of war-related trauma on normative development and urged researchers to move beyond the documentation of distress symptoms and place a greater emphasis on examining the impact that war, violence, and dislocation has on children's development (see also Richters & Martinez, 1993).

Even as a number of researchers have alluded to the potential effects that war and political violence are likely to have on children's moral development (e.g., Cairns & Dawes, 1996; Dawes, 1994; Garbarino & Kostelny, 1996; Leavitt & Fox, 1993; Macksoud & Aber, 1996; Punamäki, 1996), systematic research about these issues has been limited and its findings have been mixed, with some studies indicating that the moral development of children living in the midst of political violence is truncated, as evidenced in lower levels of moral reasoning, and others suggesting that the moral development of these youths is not negatively affected (for comprehensive and critical reviews of this research, see Cairns, 1996; Garbarino & Kostelny, 1993). The mixed nature of these findings may in part be due to the fact that the existing evidence was obtained largely on the basis of global assessments of stages of moral reasoning, with the underlying question being whether children in communities characterized by political violence reason at lower, less mature, stages than children in nonviolent communities.

The limitations of global assessments of moral stages have been exposed by moral development research conducted in the past several decades (Turiel, 1998). Two reliable findings emerging from this research are potentially relevant to the present discussion. First, it has been shown that rather than developing principled moral concepts out of less mature nonmoral concerns (such as a focus on reward and punishment), children construct moral concepts on the basis of their social interactions, and thus even young children are likely to judge that it is wrong to, for example, hurt others or steal not due to fear of punishment but because of a concern with fairness and the welfare of others. The other, complementary finding was that, along with their moral understandings, children also construct understandings about other aspects of social interactions and, when facing concrete social situations, vary in how they weigh conflicting considerations (see reviews by Smetana, 2006; Turiel, 1998).

These issues are of particular relevance to the study of moral development among war-affected children because their social interactions may not facilitate the development of moral concepts. Rather, war-affected children, exposed to conditions of violence, poverty, lawlessness, and displacement, are likely to face situations in which their moral principles about, for example, not hurting others or not stealing come into potential conflict with other significant considerations, such as their own needs for food and shelter or their wish to secure justice or retribution for having been wronged. Thus, questions about the overall stage of moral reasoning of children exposed to political violence, or global comparisons between children exposed and not exposed to violence in terms of their moral stages, may not be sufficient for identifying the unique features and vulnerabilities in the moral thinking of war-affected children. Rather, two main questions are of interest. The first, most basic, question is whether, in spite of the violence and lawlessness to which they are exposed, war-affected children develop prescriptive and generalizable moral concepts bearing on justice and welfare. If they do, the second question is how they might bring these moral concepts to bear on multifaceted situations—situations that feature considerations that are relevant to life in the midst of political conflict and that might represent compelling reasons for breaching moral principles, such as concerns with survival or revenge.

Our hypotheses concerning the first question, of whether war-affected children develop moral concepts, rely on evidence about the development of moral concepts in the context of sociocultural conditions that may also be seen as adverse. Research has shown that children growing up in traditional hierarchically organized societies develop concepts about rights and autonomy in spite of the fact that their culture's discourse and practices tend to discourage such conceptions (Turiel & Wainryb, 1998), and girls and women in patriarchal societies, who are subjected to practices that enforce gender inequalities, nevertheless make judgments about the unfairness of those practices (Wainryb & Turiel, 1994). Similarly, despite explicit socialization into Communist ideology, adolescents in Mainland China develop universalizable notions of accountability and impartiality and make judgments favoring democratic principles (Helwig, Arnold, Tan, & Boyd, 2003, 2007). Together, these findings suggest that the development of moral concepts is not merely determined by cultural and societal conditions but grounded in the intrinsic features of harmful and unjust actions (Turiel, 1998). Although cultural ideologies are not the same as actual exposure to violence and injustice, our expectation was that children exposed to political violence would nevertheless develop prescriptive and generalizable conceptions of welfare and justice.

To more fully understand the second question, of how war-affected children bring their moral concepts to bear on situations underscoring concerns with survival or revenge, it might be useful to examine not only their *moral* judgments (such as whether they think it right or wrong to, for example, steal in order to fulfill basic material needs) but also their *psychological* judgments (such as their expectations about how people are likely to act or feel when facing dire economic need). Recent research has indeed demonstrated that assessments of both psychological and moral judgments yield a more complete picture of children's actual moral experiences (Wainryb, 2004; Wainryb & Brehl, 2006; Wainryb, Brehl, & Matwin, 2005).

A number of psychological judgments are of interest. These children's expectations about what people are *likely* to do (as distinct from their judgments about what people *should* do) are interesting because war-affected youths function in the midst of chronic violence and lawlessness. Therefore, their moral experiences are likely to encompass a tension between their prescriptive judgments about whether, for example, stealing is right or wrong in a particular context and their knowledge and expectations about whether people (or even themselves) are likely to steal in that context. Although research in this regard is nonexistent, our hypothesis was that war-affected children would expect people to steal and perhaps even to engage in physical harm more often in situations of survival and revenge than in situations in which those concerns are not present. Children's expectations concerning the emotional consequences of engaging in behaviors such as stealing or hurting in specific contexts are also potentially interesting because affective reactions are a salient feature of children's experiences of moral transgressions (Arsenio, Gold, & Adams, 2006). Research has shown that children's recognition of victims' sadness or anger, deemed central to their moral thinking, emerges very early on. Their understanding that transgressors may experience shame or guilt emerges relatively late, and up to about the age of 5 or 6, children tend to think that transgressors feel happy; when present in late childhood or adolescence, however, such "happy victimizer" attributions are predictive of restricted social competence or even psychopathology (Arsenio et al., 2006). Given the importance of these psychological understandings for moral functioning, it bears asking how children who have experienced widespread violence and injustice might construe the emotional experiences of those who steal or inflict harm because of concerns with survival and revenge.

In regard to their moral judgments about stealing and harm in such contextualized situations, previous research (Helwig, 1995; Turiel & Wainryb, 1998) led us to expect that war-affected children would judge those acts to be morally wrong in unconflicted situations but would endorse stealing more frequently in situations underscoring matters of survival. It was harder to predict whether war-affected children would endorse the infliction of physical harm on others in situations underscoring concerns with revenge. While research conducted with typically developing children suggests that by middle childhood, children condemn physical retaliation and revenge (e.g., Smetana, Campione-Barr, & Yell, 2003), it has also been shown that, when provocation occurs, aggressive children and adolescents tend to view physical aggression as morally justified (Astor, 1994; Gibbs, 2003).

One additional question of interest concerns the potential age and gender differences in the judgments of war-affected children. Previous research suggests that the long-term effects of violence exposure are moderated by age and gender. Given that the maturity of physiological systems and cognitive and sociocognitive abilities may pose both vulnerabilities and protective features at each level of development, it is not surprising that the data on age differences in children's responses to violence are inconsistent, with some studies suggesting that younger children show more disturbances and others finding that adolescents exhibit the most symptoms (e.g., Wright, Master, & Hubbard, 1998). Thus, although moral development research has shown that children develop moral concepts at a young age, it is hard to predict what differences, if any, may exist in the reasoning of children and adolescents growing up in a violent society. The potential effects of gender are similarly complicated, as research suggests that boys and girls respond differently to trauma, with externalizing problems being more prevalent among boys and internalizing problems among girls (Wright et al., 1998).

Method

Setting and Participants

Colombia has been in a state of civil war for more than 50 years, with leftist guerrilla groups and rightist paramilitary groups waging war against the government and against each other. The ongoing conflict has been characterized by widespread violence, resulting in one of the highest kidnapping and homicide rates worldwide (World Bank, 2000). As a result of this conflict, nearly 4 million people (out of a population of 44 million) have been forced to leave their homes and towns, seeking refuge in the big cities. More than 400,000 of these internal refugees have relocated in shanty towns in the outskirts of Bogotá—a startling number given that the capital's total population is 8 million—creating peripheral rings of squatter settlements characterized by high population density, poor housing, lack of public services, and inadequate nutrition. Employment opportunities for internally displaced persons are particularly low, largely because more than 80% of them had been peasants prior to their displacement and lack knowledge about urban job opportunities. War-displaced children also face significant hurdles in continuing their education, both as a direct consequence of their status as displaced, as when they are required to produce forms of identification they no longer possess, and because they cannot meet the expenses associated with attending school. Thus, it is not surprising that only about 8% of displaced children are enrolled in school as compared to 93% of school-age children native to those communities (Human Rights Watch, 2006).

The present study was carried out in Usme, one of southern Bogotá's poorest slums (population 230,000) featuring one of the largest concentrations of displaced persons. Usme is a vast warren of concrete homes and plywood-and-aluminum shacks. Only some roads are paved, and in many places, people have to walk through mud and sewage. Sanitation is poor and access to water and electricity sporadic (e.g., during the time we conducted interviews, the water supply was cut off for days at a time). By Colombian socioeconomic status (SES) standards, individuals residing in Usme are classified in the "low" (*nivel bajo*, Strata 2) and "low-low" (*nivel bajo-bajo*, Strata 1) levels, characterized as living under extreme poverty. Usme is considered one of the most dangerous localities in Bogotá, with a rate of 3.3 violent deaths per 10,000 (Red Bogotá, 2006). Participants in the study were 96 displaced children (mean age = 7.7, range = 6.0–9.8), and adolescents (mean age = 14.6, range = 13.0–16.9), evenly divided by gender and age. About 40% of participants reported having lived in Usme for 1 year or longer, and the remaining had been in Usme for less than a year; however, because displaced persons often move from one neighborhood to another, the total time since *first* displacement is not known. Although most participants reported being enrolled in school (89%) and not working (88%), these figures may not be reliable because children are expected to attend school, and it is illegal for them to hold a job. Although reliable figures could not be obtained, many of the participants in the study lived alone, with siblings or peers, had no parents, or lacked contact with them.

Procedures and Assessments

Displaced children and adolescents residing in or near Usme were invited to participate in the study by the director of Cooperemos D.P.S., a nongovernmental organization (NGO) that assists displaced persons in Bogotá. Children interested in participating were asked to drop by the community center at prearranged times. Children were not offered any form of payment for their participation, but food was made available to them before and after the interview (food was not restricted to those who participated in the interview).

Waiver of parental consent was sought, as most of the youngsters likely to participate in the study either had lost their parents during the violence preceding their displacement or were solely responsible for their own survival. This is not uncommon in developing countries in South America, where children as young as 5–6 can be seen in public places, engaging in a variety of survival activities (selling candy or newspapers, washing cars, shining shoes, entertaining passers-by, begging, and scavenging; Rafaelli & Larson, 1999). In lieu of parental consent, the NGO's director agreed to act as the children's advocate. As such, the director granted consent on behalf of the entire group of children; this procedure was deemed most desirable as it did not require generating a record of the individual children's names. In addition, the agency's director (or a person designated by him) witnessed each child's assent procedure. Verbal, rather than written, consent was obtained from participants, as many of these youngsters are unable to read and write at the level required to fully understand even a simplified written document. In addition, given the ubiquity of illegal activity (including by children), youngsters are reluctant to give their full names (typically, the only agencies that require full names are government institutions where youth may be held against their will).

Following the assent procedure, children were interviewed in Spanish by the first author. Participants were given a two-part interview modeled after previous related research (e.g., Helwig, 1995; Turiel & Wainryb, 1998); the interview was conducted in one session of approximately 45 min. In the first part (general assessments), they were asked a series of questions tapping their general conceptions concerning stealing and inflicting physical harm. The purpose of these assessments was to determine whether children judge instances of harm and injustice as moral concerns, universally applicable across social contexts and not contingent on existing laws. In the second part (contextualized assessments), participants were asked to make psychological and moral judgments about stealing and inflicting physical harm in specific contexts featuring concerns with survival and revenge. The purpose of these assessments was to determine whether, and how, general moral concepts are applied in situations involving conflicts with considerations that may serve, in the sample studied, as reasons for breaching moral principles. Interviews were tape-recorded and later transcribed for analysis. Following the interview, a measure of participants' exposure to violence was obtained. Details about each set of assessments follow.

General assessments. Participants were asked to make judgments about the acceptability of stealing and inflicting physical harm ("Is it okay or not okay to [take other people's things/shove, kick, or hurt others]? Why?"). Next, they were asked whether they endorse laws against stealing and inflicting harm in their own country ("Do you think that there should be a rule against [taking other people's things/shoving, kicking, or hurting others]?") and in other countries ("Do you think that there should be a rule like that in all countries?"), and whether their judgments about stealing and physical harm are contingent on laws or common practice ("If there were no rules against [taking . . ./shoving . . .], would it be okay or not okay for someone to [take . . . /shove . . .]?" "In a country where it is very common for people to [take.../shove...], do you think it would be okay or not okay for someone to do that?"). All assessments were given first for stealing and next for inflicting harm.

Contextualized assessments. Children's psychological and moral judgments about stealing and inflicting physical harm were subsequently assessed in two contextualized conditions in which concerns with either survival or revenge were underscored; a baseline (unconflicted) condition, in which moral concerns were not pitted against other considerations, was also included for comparison. Examples of stimuli follow:

Baseline condition: Luis is 14 years old; he lives in northern Bogotá. One evening he was walking back home from the movies; the street was deserted. As he started crossing the street, he saw a guy about his age who was walking a bike. It was a good bike and it looked almost new; Luis thought that was a cool bike. His parents had told him that he could get a bike like that for his next birthday but that was still 8 months away, and Luis had wanted a bike for a long time.

Survival condition: Juan is 13 years old; he lives in Soacha. One evening he was walking back home; it was getting dark, and the street was deserted. Juan was feeling worried. A friend helped him get a job delivering newspapers and Juan needs the job to help feed his younger brothers and sisters, but to deliver newspapers he needs a bike. Bikes are awfully expensive and Juan does not have enough money to buy one. As he's thinking about this, he sees a guy about his age across the street; the guy is walking a bike. It's a good bike and it looks almost new.

Revenge condition: Julio is 15 years old; he lives in Ciudad Bolivar. One evening he was walking back home from the store. There were no people in the street. Julio was thinking about his old friends and about the house where he used to live in with his family before they had to move. As he looks up to cross the street, he sees a guy not much older than him. Julio had seen that guy before, he's one of "them," the people who hurt his father and his brother and forced his family to move. The guy is walking a bike; it's a good bike, and it looks almost new.

For each condition, psychological and moral judgments were assessed. Participants were first asked to predict the protagonist's likely course of action (e.g., "What do you think Juan is going to do? Why do you think he might do that?"). Next, they were told that the protagonist engaged in stealing (e.g., "Juan followed him quietly and when the guy was distracted, Juan grabbed the bike and rode away") and were asked to predict what the protagonist and victim might have felt (e.g., "How do you think Juan felt after he grabbed the other's guy bike and rode away?" "How do you think the other guy felt when Juan grabbed his bike?") and to judge the protagonist's behavior (e.g., "Do you think it was okay or not okay for Juan to grab the guy's bike? Why?"). Finally, participants were told that the protagonist also inflicted physical harm on the other character (e.g., "Let's say that Juan followed the guy and when he had an opportunity, he shoved him down to the ground, kicked him really hard, grabbed the bike and rode away."), and the same assessments (protagonist's emotion, victim's emotion, and protagonist's behavior) were obtained.

The three conditions were presented in a fixed order (baseline, survival, and revenge). To allow for generalizability across content areas, and to sustain participants' interest, three comparable versions were designed. In addition to the scenario dealing with a bike, another scenario dealt with a jacket and a third one with a boom box. The "jacket" and "boom box" versions of the baseline and revenge conditions were identical to the "bike" version (i.e., in the baseline condition, protagonist desired the jacket/boom box; in the revenge condition, protagonist noticed a member of the group responsible for her/his displacement wearing a jacket/carrying a boom box). For the purpose of presenting a jacket or boom box as related to survival, the "jacket" version stated that: "Juan knows that he has grown up a lot in the last six months and his clothes don't fit him anymore, they're too tight, especially his jacket. But he can't buy a new jacket now; at home they have barely enough money for food." The "boom box" version of the survival condition stated that: "Juan's grandma is so sick, she's stuck at home all alone all day. And now that the old radio broke down, there's nothing to keep her company. But he can't buy a new radio for her; at home they have barely enough money for food." Each participant heard each condition with a different scenario (e.g., baseline/bike; survival/jacket; revenge/boom box). Half of the participants in each age and gender group heard the stimuli with two male characters and the other half with two female characters. The interview was written in English, and then translated into Spanish by the first author, and back-translated by a bilingual research assistant.

Exposure to violence assessment. For the purpose of documenting the type and extent of violence exposure in this sample, participants were given the Spanish version of the Exposure to Violence interview (ETV; Selner-O'Hagan, Kindlond, Buka, Raudenbush, & Earls, 1998). The ETV is a structured interview assessing 24 types of violence (e.g., being attacked with a weapon, hearing gunfire) experienced as witness and as victim; six items (e.g., bearing on natural catastrophes, suicide) were omitted because they were deemed irrelevant. Exposure scores as "witness" and "victim" and a total ETV score were calculated based on the number of items endorsed. The ETV has a reported test – retest reliability of .75 – .94 and internal consistency indices, as measured by Cronbach's alphas, from .68 to .93.

Scoring and Reliability

General assessments. Two aspects of participants' judgments were scored using categories adapted from the widely used Davidson, Turiel, and Black (1983) scoring system. Evaluations were scored on a 3-point scale. *Evaluations* that stealing and inflicting harm (a) are wrong, (b) should be illegal in their own country, (c) and in other countries, (d) regardless of existing rules, (e) and of common practice, were assigned a score of 3; evaluations that stealing and inflicting harm are not wrong, should not be illegal in their own or other countries, or that their status is contingent on existing rules or common practice were assigned a score of 1; mixed evaluations (e.g., it is both right and wrong) on any of these assessments were assigned a score of 2. *Justifications* were scored using the following categories: welfare (e.g., "because it's wrong to punch people, it can hurt them badly"), justice (e.g., "because it isn't fair to just take something that doesn't belong to you"), and rules/punishment (e.g., "because the police will throw you in jail"). Multiple justifications were scored in terms of the proportional use of each category.

Contextualized assessments. Categories used for scoring the *expected course of action* were derived from scoring pilot data and 20% of this study's protocols. Responses were first scored as non violence (e.g., "she will borrow it from someone"), stealing (e.g., "he will just take it and run"), or violence against persons (e.g., "he will knock him down and hit him"). Next, *reasons* given for the expected course of action were scored using categories such as needs (e.g., "because his brothers and sisters were hungry"), retribution (e.g., "because this guy hurt his family and took away everything, so he's getting his revenge"), hate (e.g., "because she hates these people"), justice (e.g., "because it wouldn't be fair if he just stole it"), likes and desires (e.g., "because she really liked that bike"), and prudence (e.g., "because if he does something to him, then the other guy's friends will come and hurt him worse"). Multiple reasons were scored in terms of the proportional use of each category. The protagonist's and victim's *emotions* were scored using categories adapted from previous scoring systems (Arsenio et al., 2006), including guilt/shame, fear, sadness, anger, hate, and happiness. Responses combining two negative emotions (e.g., "she felt guilty and also angry") were scored in terms of the proportional use of each emotion category. Responses combining a positive emotion and a negative emotion (e.g., "he felt happy but also must've felt guilty") were scored into one of the two mixed-emotion categories, suggesting a combination of satisfaction and a moral emotion (happiness + guilt/shame) or of satisfaction and a nonmoral emotion (happiness + fear or hate). The evaluations of the *protagonist's behavior* were scored on a 3-point scale as *positive* (1), *mixed* (2), or *negative* (3). Justifications were scored using categories adapted from the Davidson et al. (1983) system, including welfare/justice (e.g., "it's not fair what Ines did, it's not her boom-box, it's not fair to just steal it"), rules/punishment (e.g., "it's not okay because the other guy could go to the police and he might get caught"), and retaliation (e.g., "I think it's okay, he deserves it, because he was the one that hurt Julio's family in the first place"). Multiple justifications were scored in terms of the proportional use of each category.

Scoring reliability was assessed through the independent rescoring of 20% of the protocols by a second Spanish-speaking scorer. Interjudge agreement was 99% (Cohen's $\kappa = .95$) for general assessments, 99% (Cohen's $\kappa = .98$) for expected course of action, 86% (Cohen's $\kappa = .82$) for reasons, 93% (Cohen's $\kappa = .91$) for emotions, 99% (Cohen's $\kappa = .95$) for moral evaluations, and 88% (Cohen's $\kappa = .86$) for justifications.

Results

Exposure to Violence

Findings from the assessment of violence exposure are presented first so as to better frame the main findings of the study. Table 1 shows the percentage of participants reporting having been witnesses to or victims of different types of violent events. ETV scores ranged from 1 through 17, with a mean of 7.30 (*SD* = 3.3) and a mode of 9.00. As shown in Table 1, nearly all participants (92%) reported having heard gunfire. A majority also reported witnessing someone being hit or punched (83%), chased (63%), or threatened with bodily harm (61%), and hearing that someone was killed (65%). No less important are the findings about participants who reported having witnessed the most severe types of violence, such as finding a dead body (48%), or witnessing someone being killed (30%), attacked with a weapon (39%), or being shot at (32%) or shot (34%). Indeed, the large majority (88%) of participants reported being exposed to at least one of the most severe types of violence, 70% reported being exposed to two different types of severe violence, and 52% to three or more. As would be expected, victimization rates were lower than witnessing rates. About half of the participants reported having been hit or punched (46%), and a minority also reported having been chased (29%), threatened (28%), or attacked with a weapon (8%). Analyses of variance (ANOVAs) of the mean ETV scores (also reported in Table 1) by age and gender yielded significant age effects, with adolescents reporting higher exposure rates in general, $F(1, 92) = 11.79$, $p < .001$, $\eta_p^2 = .12$, as well as higher rates for witnessing, $F(1, 92) = 11.18$, $p < .001$, $\eta_p^2 = .11$, and victimization, $F(1, 92) = 4.70$, $p < .05$, $\eta_p^2 = .05$. A gender effect was found only for victimization, with males ($M = 1.44$, $SD = 1.3$, range $= 0-5$) reporting having been victims of more types of violent incidents than females ($M = 0.85$, $SD = 1.0$, range $0-3$), $F(1, 92) = 6.40$, $p < .01$, $\eta_p^2 = .07$.

Table 1
Percentage of Participants Reporting Having Witnessed and Having Been Victims of Different Types of Violent Acts and Mean Scores of Exposure to Violence

Type of violence	Witness	Victim
Was hit/slapped/punched	83	46
Was chased	63	29
Was threatened	61	28
Was attacked with a weapon	39	8
Was shot	34	1
Was shot at	32	4
Found a dead body	48	—
Saw someone being killed	30	—
Heard that someone was killed	65	—
Heard that someone was shot	29	—
Heard gunfire nearby	92	—
Witness ETV score, *M* (*SD*)		
Children	4.94 (2.2)	
Adolescents	6.50 (2.4)	
Victim ETV score, *M* (*SD*)		
Children	0.90 (0.9)	
Adolescents	1.40 (1.4)	
Total ETV score, *M* (*SD*)		
Children	6.2 (2.7)	
Adolescents	8.4 (3.6)	

Note. The dash indicates the areas do not exist in the Exposure to Violence interview (ETV).

Analytic Strategy of Interview Data

ANOVAs were used to analyze participants' evaluations of the general assessments and of the protagonist's behavior, all scored in terms of 3-point ordinal scales. GLM procedures were adopted for analyzing participants' justifications, expected course of action, reasons, and emotions (each scored in terms of the proportional use of various categories). Although loglinear- and structural equation modeling (SEM)-based procedures are typically deemed most appropriate for analyzing categorical data, the sparseness of this study's data set poses unique challenges to these procedures because they rely on computations within cells, thus crashing when encountering zeros. Analyses made using loglinear procedures come to a halt due to the impossibility of logging zeros (see, e.g., Wainryb, Shaw, Laupa, & Smith, 2001). Sparseness becomes a challenge for SEM when modeling the data by specifying relevant latent factors. Indeed, when attempts were made to model the present data, the latent factors resulted in untrustworthy solutions (e.g., negative variance) and no model converged with acceptable results. Although analyses using a one-parameter RASCH model worked in some cases (yielding findings identical to those obtained with GLM), they too failed when encountering cells with zeros. GLM gets around this problem because it computes variability across all cells, thereby capitalizing on the fact that sparseness is cell dependent. (Note that sparseness in this case is theoretically predicted and is not a result of a coding scheme that is inappropriate or failing to capture the data.) Although, in relying on GLM, assumptions about the nature of the covariance matrix are violated, evidence indicates that this violation of assumptions is likely to produce a more conservative test of the hypotheses (Kupek, 2006). Furthermore, it should be noted that where more appropriate tests (such as RASCH analyses) can be used, the results are identical with those produced by GLM.

Preliminary analyses by "version" yielded no significant effects or interactions; "version" was thus dropped from all subsequent analyses. For all analyses, post hoc comparisons using Bonferroni *t* tests were performed to test for significant within-subjects effects. Checks for skewness and kurtosis were conducted and, where appropriate, arcsine and logarithmic transformations were used. Analyses with transformed and untransformed data yielded identical results; results are presented with the untransformed data.

General Assessments

All participants judged that it is wrong to steal and hurt others. Repeated measures ANOVAs by age, gender, and transgression (stealing – inflicting harm), with transgression as a repeated measure, were performed on participants' evaluations of the other moral criteria. As shown in Table 2, the large majority of participants of all ages stated that there should be laws against stealing and causing physical harm to others and that it would be wrong for people to steal or hurt others even if such laws did not exist or if those actions were common in a specific context. Although the majority also judged that laws against stealing and hurting should exist in all countries, adolescents (96%) did so more often than children (75%), $F(1, 92) = 9.06$, $p < .01$, $\eta_p^2 = .09$. No significant effects or interactions involving gender were found. In justifying their evaluations, the large majority of participants referred to moral concerns with justice and welfare. A multivariate analysis of variance (MANOVA) conducted on the proportional use of each justification category by age, gender, and transgression yielded a significant effect for type of transgression ($p < .001$). Follow-up ANOVAs indicated that concerns with fairness were raised to justify the negative evaluations of stealing (62%) more often than those of inflicting harm (22%), $F(1, 91) = 42.53$, $p < .001$, $\eta_p^2 = .32$, whereas concerns with welfare justified negative evaluations of harm (55%) more often than those of stealing (13%), $F(1, 91) = 60.32$, $p < .001$, $\eta_p^2 = .40$. Only a minority of participants justified their negative evaluations of stealing (24%) and harming (20%) on the basis of nonmoral reasons (i.e., rules and punishment).

Table 2

Evaluations of Moral Criteria for Stealing and Inflicting Harm (Percentages and Means)

Moral criterion	Stealing	Inflicting harm
It is wrong		
%	100	100
M (SD)	3.00 (0.00)	3.00 (0.00)
It should be illegal in our country		
%	99	100
M (SD)	2.98 (0.20)	3.00 (0.00)
It should be illegal in all countries		
%	86	97
M (SD)	2.71 (0.71)	2.94 (0.35)
It would be wrong even if legal		
%	100	100
M (SD)	3.00 (0.00)	3.00 (0.00)
It would be wrong even if commonly practiced		
%	99	100
M (SD)	2.98 (0.20)	3.00 (0.00)

Note. Means are based on a 3-point scale; higher numbers indicate decreasing acceptability for acts and increasing acceptability for laws.

Contextualized Assessments

Expected course of action. Participants were asked to predict what the protagonist might do; their responses were coded as behaviors involving no violence, stealing, or violence against persons (see Table 3). A MANOVA conducted on the proportional use of each course of action by age, gender, and condition (baseline – survival – revenge), with condition as a repeated measure, yielded significant effects for age ($p < .05$) and condition ($p < .001$), as well as an Age × Condition interaction ($p < .001$). No significant effects or interactions involving gender were found. In general, participants expected a nonviolent course of action (e.g., "she will ask her if she can borrow the bike") more frequently in the baseline condition (54%) than in the survival (13%) or revenge (16%) conditions, $F(2, 182) = 38.93$, $p < .001$, $\eta_p^2 = .30$, and expected stealing (e.g., "he will probably snatch the boom-box and ran") more frequently in the survival condition (85%) than in the baseline (45%) or revenge (57%) conditions, $F(2, 182) = 24.87$, $p < .001$, $\eta_p^2 = .22$. Notably, however, nearly half of the participants

Table 3

Expected Course of Action, by Condition and Age (Percentages)

Course of action	Baseline Children	Baseline Adolescents	Survival Children	Survival Adolescents	Revenge Children	Revenge Adolescents
Nonviolence	69	40	15	10	17	15
Stealing	31	59	82	89	66	48
Violence against persons	0	1	3	1	18	38

Note. Due to rounding, percentages may not add up to 100.

(45%) expected the protagonist to steal even in the baseline condition (i.e., when no concerns with survival or revenge were underscored)—an unexpected finding that was more marked among adolescents. Indeed, as indicated by significant Age × Condition interactions, in the baseline condition, adolescents expected stealing more often than children, $F(2, 182) = 7.31$, $p < .001$, $\eta_p^2 = .07$, whereas children expected a nonviolent course of action more often than adolescents, $F(2, 182) = 3.88$, $p < .05$, $\eta_p^2 = .04$. Although infrequent overall (10%), violent courses of action (e.g., "he'll be so angry he'll probably kick the guy"; "I bet he will want to hurt him and see him suffer") made up nearly one third (28%) of responses in the revenge condition but only 1%–2% of responses in the other two conditions, $F(2, 182) = 46.14$, $p < .001$, $\eta_p^2 = .34$. This was, again, more marked among adolescents (38%) than among children (18%), $F(2, 182) = 6.80$, $p < .001$, $\eta_p^2 = .07$.

Participants were also asked to explain why they expected such a course of action (see Table 4). A MANOVA conducted on the proportional use of each reason by condition, age, and gender yielded significant effects for age ($p < .01$) and condition ($p < .001$), as well as an Age × Condition interaction ($p < .001$). As shown in Table 4, the expected course of action in the survival condition was justified largely (76%) in terms of needs (e.g., "I think it's because she doesn't have any money and she's desperate to help her family") and the expected course of action in the revenge condition was justified in terms of retribution (e.g., "because that guy hurt his family so he's getting back at him"; 56%) and, to a lesser extent, hate (e.g., "I think because you get to hate people if they take everything away that you love"; 12%). Reasons related to need were more common in the survival condition than in the other conditions, $F(2, 182) = 160.12$, $p < .001$, $\eta_p^2 = .64$, and reasons related to both retribution, $F(2, 182) = 159.19$, $p < .001$, $\eta_p^2 = .64$, and hate, $F(2, 182) = 20.52$, $p < .001$, $\eta_p^2 = .18$, were more common in the revenge condition than in the other conditions. As indicated by Condition × Age interactions, adolescents, more often than children, referred to needs in the survival condition, $F(2, 182) = 6.05$, $p < .01$, $\eta_p^2 = .06$, and to retribution, $F(2, 182) = 3.10$, $p < .05$, $\eta_p^2 = .03$, and hate, $F(2, 182) = 9.34$, $p < .001$, $\eta_p^2 = .09$, in the revenge condition.

Table 4

Reasons for Expected Course of Action, by Condition and Age (Percentages)

Reasons	Baseline Children	Baseline Adolescents	Survival Children	Survival Adolescents	Revenge Children	Revenge Adolescents
Needs	13	3	67	84	12	3
Retribution	0	0	0	0	48	65
Hate	0	0	1	1	4	20
Justice	42	31	2	6	1	3
Likes/desires	31	59	26	7	22	1
Prudence	4	0	2	0	9	8
Other/unelaborated	10	6	2	2	4	0

Note. Due to rounding, percentages may not add up to 100.

Findings concerning the reasons for the course of action in the baseline condition were more unexpected. Whereas participants justified nonviolent expectations in terms of justice (e.g., "because it would be just wrong for her to grab it and run, it wouldn't be fair"), their expectations of stealing were justified, not in terms of needs, but in terms of likes and desires (e.g., "because he really wanted it and he didn't want to wait"). Justice reasons, $F(2, 182) = 35.95, p < .001, \eta_p^2 = .28$, and likes and desires, $F(2, 182) = 22.99, p < .001, \eta_p^2 = .20$, were given more frequently for the baseline condition than for the other conditions. As indicated by a significant Condition × Age interaction, $F(2, 182) = 12.75, p < .001, \eta_p^2 = .12$, however, adolescents provided reasons related to likes and desires more often than children in the baseline condition, but in the other two conditions children provided these reasons more frequently than adolescents.

Protagonist's emotions. Subsequent to eliciting their thoughts about the protagonist's expected course of action, participants were told that the protagonist (a) stole from or (b) incurred in physical violence against the other character and were asked to predict what the protagonist may have felt following each transgression. The distribution of emotions attributed to the protagonist is presented in Table 5. Our expectation was for participants to think that the protagonist might experience either negative moral emotions (e.g., guilt, shame) or a mixture of such moral emotions along with more positive emotions (especially in the survival and revenge conditions). As shown in Table 5, only about 40% in the baseline and survival conditions and less than 30% in the revenge condition expected the protagonist to feel negative moral emotions. Although participants often attributed mixed emotions to the protagonists, and did so in all conditions (36%–38%), about one third of the mixed emotions did not include a moral emotion but rather conveyed a mixture of happiness and either fear or hate.

The MANOVA conducted on the proportional use of each emotion category by condition, transgression, age, and gender (with condition and transgression as repeated measures) yielded significant effects for condition ($p < .001$) and age ($p < .001$), as well as a Condition × Age interaction ($p < .001$), and a significant effect for type of transgression ($p < .001$). Protagonists were said to feel guilt or shame, $F(2, 182) = 13.07, p < .001, \eta_p^2 = .13$, or a mixture of guilt or shame and happiness, $F(2, 184) = 5.77, p < .01, \eta_p^2 = .06$, more often in the baseline and survival conditions than in the revenge condition. By contrast, hate, $F(2, 182) = 16.03, p < .001, \eta_p^2 = .15$, or a mixture of hate or fear and happiness, $F(2, 184) = 9.38, p < .001, \eta_p^2 = .09$, were more commonly attributed to protagonists in the revenge than in the other two conditions. As indicated by significant Condition × Age interactions, adolescents attributed to protagonists in the revenge condition both hate, $F(2, 182) = 10.37, p < .001, \eta_p^2 = .10$, and happiness, $F(2, 182) = 6.43, p < .01, \eta_p^2 = .07$, more often than children did, whereas children, more often than adolescents, attributed to these protagonists guilt or shame, $F(2, 182) = 8.42, p < .001, \eta_p^2 = .09$. Both types of mixed emotions were more commonly attributed by adolescents than by children: Adolescents, more often than children, attributed to protagonists a mixture of happiness and guilt/shame in the baseline and survival conditions, $F(2, 184) = 5.16, p < .01, \eta_p^2 = .05$, and a mixture of happiness and hate/fear in the revenge condition, $F(2, 184) = 8.32, p < .001, \eta_p^2 = .08$.

Different emotions were also attributed to protagonists depending on the type of transgression they

Table 5
Protagonist's Emotion, by Condition and Age, and by Transgression Type (Percentages)

	Condition and age							
	Baseline		Survival		Revenge		Transgression type	
Emotion	Ch	Ad	Ch	Ad	Ch	Ad	Stealing	Harming
Guilt/shame	48	34	50	35	47	8	30	44
Hate	1	5	1	2	3	21	5	6
Fear	15	10	13	11	16	2	12	10
Happiness	10	4	13	3	9	17	12	7
Guilt/shame + happiness	19	42	18	33	18	18	32	17
Hate or fear + happiness	6	5	7	12	7	32	9	14
Other	2	1	0	4	0	2	1	2

Note. Due to rounding, percentages may not add up to 100. Ch = children; Ad = adolescents.

Table 6
Victim's Emotion, by Condition and Age (Percentages)

	Baseline		Survival		Revenge	
Emotion	Children	Adolescents	Children	Adolescents	Children	Adolescents
Sadness	80.8	46.6	80.6	50.9	85.4	42.2
Anger	6.3	36.0	5.3	30.8	6.8	41.6
Fear	6.8	15.2	10.0	17.2	6.8	13.7
Other	6.3	2.2	4.3	1.1	1.1	2.1

Note. Due to rounding, percentages may not add up to 100.

were said to have incurred. Whereas a mixture of happiness and guilt or shame was more commonly attributed to protagonists said to have stolen from, rather than inflicted harm on, the victim, $F(1, 92) = 18.74, p < .001, \eta_p^2 = .17$, a mixture of happiness and hate or fear was more commonly attributed to protagonist said to have inflicted harm on, rather than stolen from, the victim, $F(1, 92) = 4.12, p < .05, \eta_p^2 = .04$. Negative moral emotions (guilt and shame) were also more commonly attributed to protagonists who inflicted harm on, rather than to those who stole from, the victim, $F(1, 91) = 24.52, p < .001, \eta_p^2 = .21$.

Victim's emotions. Participants were also asked what the victim might have felt (see Table 6). The MANOVA involving the proportional use of each emotion category by condition, transgression, age, and gender yielded a significant effect for age ($p < .001$). Although sadness was the emotion most commonly attributed to victims across all conditions and transgression types, children referred to the victim's sadness more often than adolescents, $F(1, 87) = 38.54, p < .001, \eta_p^2 = .31$. Adolescents, in turn, attributed anger to victims more often than children, $F(1, 87) = 36.14, p < .001, \eta_p^2 = .29$.

Protagonist's behavior. Finally, participants were asked to evaluate the protagonist's behavior. An ANOVA by age, gender, condition, and transgression, with condition and transgression as repeated measures, was conducted on participants' evaluations. In general, participants negatively evaluated both stealing and inflicting harm across all conditions. However, as shown in Table 7, participants made less negative evaluations of the protagonist's behavior in the revenge condition than in the other two conditions, $F(2, 184) = 36.76, p < .001, \eta_p^2 = .29$. Although children and adolescents did not differ significantly in their evaluation of the protagonists' behaviors, there was a tendency for adolescents to be more accepting of these behaviors in the revenge condition, $F(2, 184) = 2.41, p < .09$. It is important to underscore that there were no participants who judged that it was okay for the protagonist to steal from or inflict harm on the other character in the baseline or survival conditions, and only 1 or 2 participants in each condition gave mixed evaluations (i.e., it is okay and not okay). For the revenge condition, by contrast, 19% approved of the protagonist's stealing and 21% approved of his/her inflicting physical harm, and an additional 3%–10% gave partially positive (mixed) evaluations of those behaviors.

Participants were also asked to justify their evaluations (see Table 8). The MANOVA involving the proportional use of each justification category by age, gender, condition, and transgression yielded significant effects for age ($p < .001$) and condition ($p < .001$). Participants' negative judgments of

Table 7
Mean Evaluations and Percentages of Negative, Mixed, and Positive Evaluations of the Protagonist's Behavior, by Condition and Transgression Type

	Condition and transgression type					
	Baseline		Survival		Revenge	
	Stealing	Harming	Stealing	Harming	Stealing	Harming
M (*SD*)	2.99 (0.10)	3.00 (0.00)	2.98 (0.14)	2.99 (0.10)	2.54 (0.79)	2.55 (0.82)
% negative evaluations	99	100	98	99	71	76
% mixed evaluations	1	0	2	1	10	3
% positive evaluations	0	0	0	0	19	21

Notes. Means are based on 1 = *okay*, 2 = *okay and not okay*, 3 = *not okay*.

Table 8
Justifications for Evaluations of the Protagonist's Behavior, by Condition (Percentages)

	Condition		
Justification	Baseline	Survival	Revenge
Welfare/justice	65	64	27
Rules/punishment	23	22	39
Retribution	0	1	24

stealing and causing harm in the baseline and survival conditions were justified largely in moral terms. Indeed, moral concerns with welfare and justice were more common in the baseline and survival conditions than in the revenge condition, $F(2, 182) = 49.43$, $p < .001$, $\eta_p^2 = .35$. Still, it should be noted that, somewhat unexpectedly, around 20% of participants who made negative evaluations of the protagonist's behavior in the baseline and survival conditions, did so for nonmoral reasons (e.g., "it wasn't okay for him to steal the bike because he might get caught and get in trouble"). This unexpected tendency was even more marked in participants' reasoning about the revenge condition. In this case, even though between 71% and 76% of participants had evaluated the protagonist's stealing and inflicting harm negatively, only 27% did so for moral reasons (e.g., concerns with the victim's welfare or with justice); 39% relied, instead, on references to rules and punishment (e.g., fearing punishment or further retribution). Indeed, concerns with rules and punishment were more common in the revenge condition than in the other two conditions, $F(2, 182) = 11.02$, $p < .001$, $\eta_p^2 = .11$. Concerns with retribution were also more common in the revenge condition than in the other two conditions, $F(2, 182) = 37.99$, $p < .001$, $\eta_p^2 = .29$, and were used largely to justify participants' positive evaluations of the protagonist's behavior. Finally, significant age effects indicated that, in general, adolescents (62%) referred to concerns with welfare and fairness more often than children (42%), $F(1, 91) = 13.45$, $p < .001$, $\eta_p^2 = .13$, and children (37%) referred to concerns with rules and prudence more often than adolescents (19%), $F(1, 91) = 10.26$, $p < .01$, $\eta_p^2 = .10$.

Discussion

Undeniably, children and adolescents in this sample have been exposed to considerable violence. Although the rates of victimization were relatively low, all participants had witnessed some form of violence perpetrated on others, with an average of 6.2 and 8.4 different types of violence, respectively, for children and adolescents, and the majority (88%) had witnessed at least one of the most severe and disturbing events, such as finding a dead body or seeing someone being shot. The finding that the prevalence rates of victimization, as compared to witnessing, were low is consistent with findings about children's exposure to violence in the United States (e.g., Richters & Martinez, 1993)—findings that have also unequivocally established the serious mental health implications of witnessing violence. Although there are no sufficient data from other war-torn countries or displaced populations to draw comparisons, the rate of exposure of our sample seems quite high. By comparison, Macksoud and Aber (1996), using a similar method, reported that, on average, Lebanese children ($N = 224$) in four demographically distinct areas had experienced six different types of violent incidents. The findings of this study thus speak about the moral realities and moral judgments of children who had grown up in the midst of severe political violence.

The first set of assessments ("general assessments") indicated that displaced children and adolescents think about matters of welfare and justice in moral terms. Indeed, participants in this study made universal and noncontingent moral judgments not unlike those of normative samples studied in the United States and other countries (Smetana, 2006; Wainryb, 2006). They thought it was wrong to steal and hurt others not because one may get punished or because it is against the law but because of considerations with justice and the welfare of others. Nearly all also judged it would be wrong to steal or inflict harm even if it were legal or common. No differences in these regards were found based on age or gender. These findings, that war-affected children and adolescents display noticeable moral knowledge in spite of having been exposed to violence, poverty, and dislocation, are incompatible with the grim picture of moral disorientation and truncated development painted by some (Fields, 1973, 1980). It appears that rather than merely taking their common experiences of violence and injustice as the sole criterion for determining what is right and wrong, war-affected children, not unlike children living in nonviolent communities across the world, make judgments in relation to what they perceive to be the intrinsic features of moral violations. Indeed, even common practice and the absence of laws do not—in their judgment—alter what is morally right and wrong. In this respect, these findings are consistent with an emerging body of data indicating that children develop prescriptive and generalizable moral concepts even in contexts that do not seem to facilitate, explicitly or implicitly, such a development. Whereas previous research (e.g., Helwig et al., 2003, 2007; Neff, 2001; Turiel & Wainryb, 1998; Wainryb & Turiel, 1994) has focused on contexts defined in terms of cultures that impede (or appear to impede) the development of certain moral concepts, the present study extends these findings to social contexts framed in terms of war and the accompanying conditions of violence, poverty, lawlessness, and displacement.

The lack of evidence of truncated development does not, however, imply that the moral development of children growing up in the midst of political violence is unaffected. Rather, the findings of this study point to the importance of examining both how war-affected children think about moral matters in general and how they bring their moral concepts to bear on specific contexts in which relevant conflicting considerations are made salient. Indeed, participants' psychological judgments about what story protagonists are likely to do and feel in specific conflict situations, and their moral judgments concerning the protagonists' moral transgressions in those situations, demonstrate that their moral concepts bear more heavily in some contexts than others.

Participants were first asked to predict what story protagonists are likely to do in the face of dire need or revenge. In spite of their negative judgments of theft and physical harm in the abstract (general assessments), 85% expected protagonists to steal in the survival condition, 85% expected them to steal or inflict harm in the revenge condition, and 45% expected protagonists to steal even in the baseline condition in which concerns with survival and revenge were not mentioned. These findings reflect, probably quite accurately, the social and interpersonal reality within which participants in our study function. People, they are telling us, steal and hurt each other even though such actions are morally wrong. Given that in responding to our queries, most participants suggested that they identified with the story protagonists (as in "If that guy were me, I'd try to take the bike and run"), these findings can also be taken to mean that participants think *they* might also steal or inflict harm on others.

In some respects, these findings are reminiscent of findings concerning girls and women in patriarchal societies, who judged that females have a right to make their own decisions and that it is wrong for fathers and husbands to curtail their daughters' and wives' freedom of choice but, at the same time, also predicted that most daughters and wives would acquiesce to the restrictions imposed on them by males in their families (Wainryb & Turiel, 1994). Arguably, as was the case with those girls and women, displaced children's acknowledgment that there are discrepancies between what should happen and what is likely to happen is both realistic and adaptive in the context of the social world within which they function. At the same time, their construal of the world as one in which people do not follow ethical principles might also have long-term implications for their ability or motivation to trust others, and indeed, themselves, to honor commitments and control their own aggression (see Garbarino & Kostelny, 1996). More research is needed to further examine these issues.

After participants stated what *they* thought the protagonists were likely to do in each condition (baseline, survival, and revenge), they were told that protagonists decided to engage in stealing and, subsequently, physical harm. Then they were asked to predict what the protagonists might feel after stealing or inflicting harm in each condition and to judge whether these actions were right or wrong. As might be expected based on research with normative samples, the large majority (86%) recognized that victims in all conditions would feel sad and, to a lesser extent, angry, and a majority also predicted that protagonists in the baseline (72%) and survival (68%) conditions would experience moral emotions (guilt or shame) or mixed emotions (a mixture of guilt or shame and happiness). These findings are important in light of the centrality attributed to children's understandings of affective reactions in the context of moral transgressions (Arsenio et al., 2006). Indeed, the fact that participants can appropriately predict the emotional states likely to ensue after stealing and hurting others—namely, that victims are negatively affected and transgressors feel remorse—bodes well for these children's capacity to bring their moral concepts to bear on at least some situations of moral transgression (Shaw & Wainryb, 2006).

Less consistent with normative data were the findings in the revenge condition. In this case, only a minority expected protagonists to experience guilt or shame (28%) or mixed emotions (18%); the remaining 54% expected protagonists to feel no moral emotions, with 33% expecting them to feel either happy or both happy and afraid or hateful. In some respects, this finding is a source for concern, as research in the United States has shown that "happy victimizer" attributions among older children and adolescents are predictive of behavioral problems and even psychopathology (Arsenio et al., 2006). It is nevertheless possible that this finding has different meanings, and thus different psychological consequences, for children in this sample. It is hard to tell what it might mean, for children who have suffered serious injury at the hands of a certain group of people, to expect not to feel remorse—or even to feel happy—upon inflicting (or thinking about inflicting) harm on them. Furthermore, it is important to recall that, in the present study, the happy victimizer attributions were restricted to the revenge condition; the very same children expected protagonists to feel shame or guilt in other conditions. It is thus possible that the consequences of this phenomenon may not be identical to those presumed to ensue among juvenile delinquents or aggressive children in the United States, for whom such attributions are more generalized.

As was the case for their expectations about what protagonists might feel upon hurting others, participants' moral judgments of protagonists' actions also varied by condition. As hypothesized, nearly all (99% – 100%) judged such actions to be morally wrong in the baseline condition, where no conflicting concerns were present. More important, and somewhat unexpectedly, nearly all (98% – 99%) also judged that it was morally wrong to steal or inflict harm on others in the survival condition, in which protagonists' dire economic needs were underscored. These judgments are particularly significant given that most participants also recognized the urgency of the underlying needs and expected that, in this condition, people would actually steal. Still, their judgments were unequivocally negative and moral—that is, they thought that it would be wrong for protagonists to steal or hurt others even if these acts were to fulfill some of their basic needs, not because protagonists might be caught or punished for doing so, but because of concerns with fairness and the well-being of the victims. The fact that their expectation that most people *would* steal did not translate into their judging that doing so is right, suggests that participants do not merely adhere to a relativistic view that "anything goes." It is furthermore unlikely that this finding—that they overwhelmingly judged stealing in the survival condition to be morally wrong—may be the result of social desirability; as seen below, their judgments of stealing and harming in the revenge condition were neither straightforwardly negative nor systematically grounded on moral terms.

Indeed, in the revenge condition, 29% and 24%, respectively, for stealing and harming, judged that it was okay, or partially okay, for protagonists to engage in such actions (e.g., "I think it's okay that he beat him up because that person had hurt his family first so he's just paying him back"), and an additional 39% stated that these actions were wrong but not for moral reasons, but rather because protagonists might be hurt or punished for engaging in said actions (e.g., "I don't think it was okay that he hit him and kicked him, you know, because then those people can come back and hurt his family all over again and even worse").

These findings, concerning participants' endorsement of harm in the context of revenge or their disapproval of revenge for selfish, rather than moral, reasons, are inconsistent with findings obtained among typically developing children in the United States. Although revenge is not a foreign concept among people in the United States, as attested, among others, by the broad support of capital punishment, in samples of school-aged children in the United States, only aggressive children tend to approve of revenge; nonaggressive children (aged 8 and older) consistently disapprove of revenge as a means for solving interpersonal problems and redressing wrongs, even when directly provoked (Astor, 1994; Smetana et al., 2003). Rather, these findings are reminiscent of early moral development findings concerning the potentially injurious effects of a depressed moral atmosphere, such as that of prison settings, where reasoning stabilizes around Stage 2 "tit-for-tat" morality (Kohlberg, Scharf, & Hickey, 1971; see also Gibbs, 2003). Recent research similarly suggests that, in sociopolitical contexts characterized by deprivation and neglect, children approve of the exclusion of certain people and endorse revenge (Ardila-Rey, Killen, & Brenick, in press; Brenick et al., 2007; Killen, Henning, Kelly, Crystal, & Ruck, 2007; Margie, Brenick, Killen, Crystal, & Ruck, 2006). It should be noted that, unlike what is assumed under the "moral atmosphere" hypothesis, our own findings as well as the more recent findings emerging from Killen's lab indicate that children's endorsement of retaliation and retribution is restricted to certain conditions. Even when thus limited, however, the construal of aggression against certain people as a legitimate means for redressing grievances and reinstating justice may be seen as a reason for concern as it is likely to contribute to the perpetuation of cycles of violence (Garbarino & Kostelny, 1993; Opotow, 1990; Opotow, Gerson, & Woodside, 2005; Wainryb & Pasupathi, in press).

The potential vulnerabilities identified in participants' thinking were more pronounced among adolescents. In fact, on nearly each dimension tested, adolescents fared more poorly than children. Adolescents predicted more stealing in the baseline condition (when considerations of need and revenge went unmentioned) and more violence against persons in the revenge condition, they referred more often to retribution and hate as reasons for expecting violence, they attributed more hate and happiness and less guilt and shame to perpetrators in the revenge condition; and they had a slightly higher tendency to be accepting of stealing and inflicting physical harm in the revenge condition. It is important to emphasize, however, that, as would be expected from a reliable body of moral judgment findings (Smetana, 2006; Turiel, 1998), children and adolescents did not differ in their *moral* concepts. Rather, concerns with retribution and revenge, in particular, seemed to weigh more heavily on adolescents' expectations and judgments. This finding may be thought to be due to adolescents' generalized tendency to focus on peer groups and loyalty or to their presumably more relativistic orientation that might lead them to attribute to others greater self-interest. However, developmental research conducted in a variety of communities not exposed to political violence, in the United States and other countries, has clearly demonstrated that adolescents do not endorse revenge (Smetana et al., 2003) or the exclusion of individuals or groups (Killen, Lee-Kim, McGlothlin, & Stangor, 2002), nor do they display a generalized relativistic orientation (Wainryb, 1993; Wainryb et al., 2001). This would suggest that the age-related findings in this study are more likely to be associated to the specific experiences of war-displaced adolescents than to broader features of adolescent thinking. As shown, repeated and prolonged exposure to violence does not protect children against negative developmental outcomes but, rather, increases their susceptibility to traumatization (e.g., Garbarino & Kostelny, 1996). Given the length of the political conflict in Colombia (over 50 years), it is reasonable to assume that adolescents had been exposed to these conditions longer than children.

In contrast to age, gender had a negligible effect. In the present sample, boys and girls did not differ in the level of violence to which they had been reportedly exposed (though boys reported a slightly higher level of victimization) or in their moral thinking. Although there are data suggesting that boys are typically exposed to more violence than girls (Wright et al., 1998), these data come largely from research conducted in inner-city neighborhoods in the United States. It may be that in situations of displacement following political violence, girls do not benefit from any significant additional protection. (There is, in fact, evidence indicating that in Colombia, girls comprise nearly half of the guerrilla units; Human Rights Watch, 2003). Although these gender-related findings cannot be taken to imply that all their experiences were necessarily identical, at least in regard to the dimensions assessed in this study, boys and girls displayed similar moral understandings and vulnerabilities.

Overall, this study's findings are not suggestive of moral disorientation or truncated development. Rather they speak about how war-affected children—children for whom violence, injustice, and dislocation are normalized, a fact of life—interpret and reason about distinct morally relevant contexts. In general, these findings unveil a reservoir of moral knowledge among these children: It appears that even the impoverished environments of war and displacement present youths with opportunities for reflecting on the intrinsic features of actions that harm others. At the same time, these findings also point to potential vulnerabilities in these children's moral lives. Concerns with survival—whose gravity participants clearly acknowledged—prevailed over moral considerations in some respects: Participants expected people to steal when faced with overwhelming need but also judged that doing so would be morally wrong. Concerns with revenge colored their expectations and moral judgments more sweepingly. It seems therefore possible that contexts underscoring concerns with survival might compromise children's ability to view themselves and others as moral agents, whereas contexts underscoring revenge might give rise to cycles of violence; future research might explore further these specific vulnerabilities. The long-term developmental implications of this pattern of vulnerabilities might also hinge on how children make sense, as a whole, of the political conflict within which their moral lives, and unique moral conflicts, are embedded. Societies tend to superimpose, on the reality of violence, different kinds of meanings—more or less coherent, more or less polarized—about, for example, the roots of the conflict and the nature of the "enemy." Whether such ideological frameworks serve as a protective factor vis-a-vis children's moral development (Barber et al., 2006) or foment further vulnerability (Cairns, 1996; Garbarino & Kostelny, 1993; Punamäki, 1996; Wainryb & Pasupathi, in press; Wessells, 2006) is another question that merits further investigation.

Pathways to Literacy: A Study of Invented Spelling and Its Role in Learning to Read

Gene Ouellette

Monique Sénéchal
Carleton University

This intervention study tested whether invented spelling plays a causal role in learning to read. Three groups of kindergarten children (mean age = 5 years 7 months) participated in a 4-week intervention. Children in the invented-spelling group spelled words as best they could and received developmentally appropriate feedback. Children in the 2 comparison groups were trained in phonological awareness or drew pictures. Invented-spelling training benefited phonological and orthographic awareness and reading of words used in the intervention. Importantly, the invented-spelling group learned to read more words in a learn-to-read task than the other groups. The finding are in accord with the view that invented spelling coupled with feedback encourages an analytical approach and facilitates the integration of phonological and orthographic knowledge, hence facilitating the acquisition of reading.

Young children often attempt to represent words in print before they can reliably read words. When children first begin experimenting with the written code, their spelling attempts may bear little resemblance to conventional spellings. Over time, these invented spellings increase in phonological accuracy and orthographic complexity as children become more adept at capturing words in print. Given that invented spelling most often emerges before children are established readers (Gentry & Gillet, 1993), it is possible that these early spelling attempts promote the development and integration of the skills that facilitate the acquisition of reading. At present, however, there is limited experimental evidence that invented spelling is indeed a valuable precursor to early word reading. The goal of the present research was to directly assess the role of invented spelling in early reading acquisition. A better understanding of the causal relation between early spelling and reading can contribute to models of early literacy acquisition as well as empirically validated approaches to early literacy education.

Children's early attempts to represent words in print prior to any direct instruction in spelling have been of interest to researchers and clinicians ever since the topic was brought to the forefront by Read (1971, 1975), Chomsky (1971), and Clay (1972), and subsequently discussed in detail by Treiman (1993). Read described how as children experimented with putting words into print, they became more adept at connecting the sounds heard to the letters produced. Hence, over time, invented spellings increase in sophistication and gradually come to resemble conventional spellings. Subsequent descriptions have revealed a progression from initial nonalphabetic markings to capturing the initial sounds, then to the initial and final sounds, and then to the appearance of medial vowels in children's invented spellings (Ferreiro, 1991; Gentry & Gillet, 1993; Henderson, 1981; Treiman, 1993; also see in Hebrew and Dutch: Levin, Both-de Vries, Aram, & Bus, 2005; Levin & Korat, 1993). In accordance with Read's original descriptions, subsequent stage theories of invented spelling have also proposed that invented spelling progresses from an initial reliance on phonology in translating what is heard into print to a later incorporation of word-specific orthography (e.g., Gentry & Gillet, 1993). Key to the concept of invented spelling is that it results from a child's own experimentation with representing words in print and it occurs naturally (Burns & Richgels, 1989; Richgels, 1995). It is not a process of memorization and recall of conventional spellings; rather, it is a developmental progression in which spelling attempts increase in phonological and orthographic accuracy over time.

This research was supported by a grant from the Social Sciences and Humanities Research Council of Canada to the second author. We thank the children, parents, teachers, and school personnel who made this study possible. We also thank Tina Leclaire and Kristen Petruska for their invaluable help with data collection.

The issue addressed in the present research is whether invented spelling allows children to develop an analytic stance to language that goes beyond phonological awareness stimulation and promotes the storage of orthographic information within lexical representations, beyond learning letter names and sounds. There has been abundant research showing that children benefit more from phonological awareness training when the intervention also includes letter knowledge training as compared to when it does not. In their meta-analytic review, Ehri et al. (2001) found 18 different phonological awareness training studies that included a letter knowledge training component and were conducted with normally developing or at-risk children in kindergarten or Grade 1. Ehri et al. reported that the overall effect sizes for these intervention studies were statistically significantly greater than those for studies that did not include a letter knowledge training component (i.e., the reported effects for the training with and without letters were 1.11 vs. 0.83, 0.67 vs. 0.38, and 0.61 vs. 0.34, for outcome measures of phonological awareness, reading, and spelling, respectively). Ehri et al. argued that letter training in conjunction with phonological awareness training allows young children to anchor the abstract notion of phonemes onto the concrete symbols that are letters. We contend that invented spelling also has this facilitative effect and more. Invented spelling may indeed help children analyze oral language into phonemes, but, very importantly, it provides an exploratory learning experience that may also promote the integration of phonological and alphabetic information into initial lexical representations. As these lexical representations become refined, they may facilitate the acquisition of reading. The importance of integrating phonology and orthography in reading acquisition is evident in the lexical quality hypothesis of Perfetti and Hart (2002), which attributes success in early word reading to the *quality* of internal lexical representations, as defined by integrated knowledge of a word's phonology, orthography, and meaning. Invented spelling, therefore, may allow children to explore and analyze the written code and begin to make these proposed important associations between phonological and orthographic representations.

In a similar vein, Frith (1985) proposed that early spelling attempts provide children with insight into the role of the alphabet in representing sounds in words, and this knowledge is later transferred to word reading. In fact, when invented spelling is included in empirical investigations, correlations suggest that invented spelling predicts early reading (Mann, 1993; McBride-Chang, 1998; Morris & Perney, 1984; Shatil, Share, & Levin, 2000). Further support for a pathway of influence from invented spelling to word reading comes from a word learning study conducted by Richgels (1995). In this experiment, kindergarten children with strong alphabetic knowledge but who were still nonreaders were classified as good or poor invented spellers. These children (n = 16) were then taught to read phonetically simplified words through a paired-associate learning task. The good invented-spelling group significantly outperformed the poor invented-spelling group in terms of the number of words learned over a 2-day period. Richgels concluded that there is a strong relation between invented spelling and learning to read at the start of schooling.

Training studies offer stringent tests of a causal relation between invented spelling and early word reading. That is, if training in one area can be shown to transfer to or facilitate growth in another, hypothesized pathways of influence can be confirmed. Following the proposed directional influence of invented spelling on word reading, training invented spelling should facilitate the acquisition of word reading (Frith, 1985; Treiman, 1998). Two studies are frequently cited as evidence that training invented spelling may improve reading: Ehri and Wilce (1987) and Uhry and Shepherd (1993). Ehri and Wilce found that kindergarten children trained to spell phonetically simplified words (e.g., *seat* spelled as *set*) learned to read similarly simplified words in fewer trials than did a control group of children. In this study, however, instruction was not tailored to the individual child's developmental level, nor did training involve spontaneous spelling attempts that are fundamental to the definition of invented spelling. In addition, the experimental group may have been more adept at learning to read simplified words because they were more familiar with similar stimuli. That is, participants in the experimental group were exposed to simplified spellings that were taught as words during the training component, whereas the control group was not.

The training program reported by Uhry and Shepherd (1993) involved teaching Grade 1 students to phonologically analyze words: A segmentation task was taught and letters incorporated as an introduction to *conventional* spellings. Impressively, trained children demonstrated transfer to word decoding and outperformed a control group of children on posttest measures of word reading. Similar results were reported by O'Connor and Jenkins (1995) with a small sample of children who had developmental delays. Although these studies highlight the importance of analytic phonological awareness and conventional spelling instruction in Grade 1, they did not directly deal with the potential pathway of influence between *invented* spelling at the start of schooling and subsequent word reading. In fact, an extensive review of the literature revealed only two training studies in which naturally occurring invented spelling was encouraged or involved in a teaching paradigm and word reading was evaluated as a posttest measure. These two studies are outlined next.

In a naturalistic educational study, Clarke (1988) compared two Grade 1 classroom programs—one that included invented spelling and one that included conventional spelling instruction. Over the school year, the classes in which invented spelling was encouraged showed the greatest improvements in both decoding and irregular word recognition. This important study establishes the relevance of invented spelling in the classroom, yet the natural classroom context of the research comes at the expense of experimenter control and internal validity. In addition, phonological awareness was not measured, and thus, it is not known if group differences were attributable to any preexisting differences in this already established influential skill.

Rieben, Ntamakiliro, Gonthier, and Fayol (2005) recently reported a carefully controlled multiple-group intervention study with 5-year-old French-speaking children. This study contrasted the effects of training invented spelling, invented spelling with corrective feedback, and copied spelling. The invented-spelling group with feedback scored significantly higher than the control group and all other experimental groups for reading practiced words. However, no between-group differences were evident for reading of words not used in the training program, and more surprisingly, no group differences were reported for measures of phonological awareness and invented-spelling complexity. The limited impact of invented spelling may be due to the fact that the 18 training sessions given to each group were spread out over 6 months, which may not have been intensive enough to promote learning. Participants' letter knowledge was also very low, which may have constrained learning across all conditions and precluded those in the invented-spelling groups from benefiting from the intervention, especially given the complexity of the reading test stimuli used.

The research reviewed so far provides some evidence that early spelling attempts influence subsequent word reading, but strong experimental evidence is still lacking (Caravolas, Hulme, & Snowling, 2001; Fletcher-Flinn, Shankweiler, & Frost, 2004; Rieben et al., 2005). The present study evaluated the benefits of training kindergarten students to be better invented spellers through a pretest, posttest, comparison group design. In addition to a group trained in invented spelling and a control group, there was also a comparison group trained in phonological awareness. Given the meta-analytic results obtained by Ehri et al. (2001), all children, including those in the phonological awareness group, also received letter knowledge training. The inclusion of a phonological awareness (plus letters) group allowed for a comparison between children trained on invented spelling and those trained on phonological awareness, a comparison that is relevant, given past assertions that invented spelling represents self-directed phonological awareness training (e.g., Mann, Tobin, & Wilson, 1987). This design allowed for a clear evaluation of group differences on key skills that were posttested, following the different interventions. In addition, a learn-to-read task was given to all participants following the intervention to assess any facilitative effects of the training on *learning* to read words. All participants were children who, at the onset of the intervention study, did not demonstrate consistent word reading ability. This allowed us to test the transfer of skills from spelling to reading without the influence of well-established, preexisting reading skills.

It was hypothesized that the training procedures implemented would prove to be efficient in that the invented-spelling group would show improved spelling sophistication relative to the other groups, whereas the phonological awareness group would show improved phonological awareness on posttest relative to the control group. Given that invented-spelling practice may involve phonological awareness, it was hypothesized that the invented-spelling group would also show a posttest advantage over the control group for phonological awareness. It was also hypothesized that the invented-spelling group would show a posttest advantage over both other groups on a task of implicit orthographic awareness. Central to the study, the invented-spelling group was hypothesized to outperform the other groups on a learn-to-read task. Although we also included a general word reading posttest measure, we did not think that a 4-week intervention would be long enough to show the transfer from invented spelling to word reading without some form of reading instruction.

Method

Participants

Participants were selected to meet a number of criteria from a sample of 145 kindergarten children who were participating in another research project (Ouellette & Sénéchal, 2008). All children used English as their primary language and were recruited from four English schools in a large Canadian city. To control for the influence of prior reading skills, children who could read more than one word from a list of five simple consonant-vowel-consonant decodable words and/or more than one word from a list of five high-frequency sight words were not considered for the present study (n = 30).

From those identified as having no or minimal word reading ability, children from each participating class were randomly assigned to one of three intervention groups if they could be matched with two other students from the same class on invented spelling, letter–sound knowledge, and phonological awareness. In all, this matching procedure resulted in 69 children (39 female and 30 male, mean age = 5 years 7 months) assigned to one of three intervention groups, creating three equivalent groups of 23 students. The mean level of education of the parent completing the permission form was some postsecondary studies (college or undergraduate courses), and parental education ranged from *not having completed high school* to *having completed postgraduate studies*. The sample was chiefly Caucasian, yet multicultural in the sense that 43.5% reported having a second language spoken in the home, which included French (27.5%), Asian (4.3%), and other European languages (11.7%). Because the matching was done within each class, classroom/teacher effects were counterbalanced across groups. In all, children were drawn from nine classes from four schools. In their kindergarten year, children in this Canadian city only attend school for half of the day, had not received direct phonics instruction beyond exposure to the alphabet, and their teachers did not follow a standard kindergarten literacy curriculum.

Measures

Invented spelling. Children were asked to spell as best they could 10 words. The words were all selected to meet a certain number of criteria. The words could be spelled by relying exclusively on a set of 13 letters; they were high-frequency words, contained relatively high-frequency biphone probabilities, and represented a variety of articulatory and syllabic features. Three of these words were taken from Tangel and Blachman (1992, 1995), whereas the remaining words were chosen to fulfill several criteria and are presented in the Appendix.

The scoring system described by Tangel and Blachman (1992, 1995) was used to evaluate the invented-spelling attempts because it is sensitive to the developmental sequence observed in descriptive studies. Each spelling attempt was scored on a 7-point scale (0–6). The scale takes into account both the number of phonemes represented and the level of orthographic representation and has excellent reported reliability. Typically, a score of 0 is given for a random string of letters, a score of 1 for a phonetically related letter used to mark a salient part of the word, a score of 2 for the correct initial grapheme, a score of 3 for representing more than one phoneme with phonetically related or conventional letters (in the proper sequence), a score of 4 for all phonemes represented with phonetically related or conventional letters, a score of 5 for all consonant phonemes represented with conventional letters and vowel presence marked, and a score of 6 for proper conventional spelling.

Interrater reliability was initially assessed by having two raters score all spelling attempts (Tangel & Blachman, 1992, 1995; Treiman & Bourassa, 2000). The percent agreement between the two raters on all 1,150 items (115 eligible children × 10 words) was 85.83%, and the Pearson correlation between the total score given to each child by the two raters was strong at r = .98. Each disagreement was reviewed by the raters until a consensus score reached. This is an important step to ensure accuracy, as 119 of 163 discrepancies were found to be scorer error, whereas the remaining 44 discrepancies were related to interpretation of the child's intended target letter. Using the final agreed-upon scores, the interitem reliability was also calculated and found to be excellent (α = .91).

Word reading. At pretest, children were asked to read 10 words to assess word reading. The word list included 5 high-frequency, irregularly spelled sight words taken from lists provided by both Fry, Kress, and Fountoukidis (2000) and Fountas and Pinnell (1996), and 5 high-frequency, decodable words. The 10 words were between two and four letters in length and are presented in the Appendix. The decodable words were also chosen based on their concreteness so that they could be easily drawn, as well as to represent various syllable structures. Words were presented one at a time in a fixed random order on separate index cards in 48-point font. The irregular words were shown first and the children asked to say what they thought the word was. For the decodable items, the children were encouraged to look at the letters, to sound them out, and to give their best guess. At posttest, 5 additional words were added. Note that the 5 decodable words from the reading pretest were stimuli used in the interventions; thus, as a posttest, they offer a measure of regular (decodable) word reading for practiced words. Five additional decodable words were added at posttest to provide a measure of regular word reading for novel words. These additional words were of the same syllable structure, composed from the same limited letter set, and contained the same vowel types as the practiced words (Appendix). The interitem reliability at posttest was very good (α = .78).

Letter–sound knowledge. Children were asked to provide the sounds made by 24 letters of the alphabet (all letters of the alphabet, except for X and Q) in addition to three digraphs (CH, SH, and TH). Each grapheme (or digraph) was printed on an individual index card in both upper and lower case 72-point Arial font. Cards were presented in a fixed random order, and the maximum score was 27. Interitem reliability was excellent (α = .87 at posttest).

Phonological awareness. Three subtests of the Comprehensive Test of Phonological Processing (CTOPP; Wagner, Torgesen, & Rashotte, 1999) were administered to assess children's awareness of phonemes in the word-initial and word-final positions, as well as their ability to delete a syllable or a phoneme from a spoken word, and to blend individually presented phonemes into words. In the Sound Matching subtest, children were shown four pictures on each trial and asked to indicate which picture either started the same or ended the same as the first picture. Each picture was also named by the experimenter upon presentation. There are 20 items in all (10 first sound matching and 10 final sound matching), but testing is stopped when the child misses 4 of 7 items. In the Elision subtest, the child repeats a word after the experimenter and is then asked to say the word again but leaving certain sounds out. For example, the child is asked to say cup without saying /k/. There are 20 items in all, with testing stopped following three consecutive errors. The Blending Words subtest requires the participant to listen to a recorded CD of a female voice, saying words phoneme by phoneme. The child is then asked to say what the intended word was. This subtest was presented via a personal CD player and headphones. There are 20 items in all, with testing stopped following three consecutive errors. Following the recommended scoring procedures of the CTOPP, scores on these subtests were converted to standard scores with a mean of 10 and then combined to create a phonological awareness composite. The reported reliability of this composite is very good (α = .79).

Orthographic awareness: Permissible sequences. Following the conceptualization of orthographic awareness encompassing visual recognition of permissible sequences within words (Levy, Gong, Hessels, Evans, & Jared, 2006), children's implicit awareness was measured with two forced-choice tasks. The tasks tapped implicit knowledge of rules because explicit knowledge of orthographic constraints is not expected at this age, nor would the children be expected to be able to verbalize these rules. The first task, referred to as *Vowels*, was adapted from Levy et al. (2006) and contrasted nonwords containing a medial vowel with nonwords lacking a vowel (10 nonword pairs). The procedure of Levy et al. was followed whereby each card containing a stimuli pair was shown and the child then asked which item looked best or which item their teacher would like to read the most. All stimuli were presented in a fixed random order on individual index cards in 72-point Arial capitalized font. The final task, named *Double Consonants*, was adapted from Cassar and Treiman (1997) and contrasted nonwords where one item contained an allowable consonant doubling at the final position and the other contained an illegal consonant doubling in the onset position. All stimuli are presented in the Appendix in the order of presentation. Performance here was close to chance for many of the children, thus preventing meaningful estimation of reliability.

Learn-to-read task. Posttesting concluded with a learn-to-read task modeled after that developed by Ehri and Wilce (1987). In this learn-to-read task, each participant was taught to read 10 decodable words in a paired-associate fashion. The words to be learned were all composed from the same letter set taught to all intervention groups and are listed in the Appendix. Five words started with *B* and 5 with *P*, thus requiring the children to pay attention to more than just the initial consonant. These words represent a range of common syllable types used in early reading instruction and include words of varying difficulty, with the inclusion of a consonant blend and bi-syllabic word. Children, therefore, had to attend to all letters in the words, and this small set of words allowed for their learning proficiency to be evaluated over a range of syllable types and complexity.

The procedure was adapted from that outlined by Ehri and Wilce (1987). The task began with a study trial in which children were told that they were going to learn to read some words and that the words contained the letters that they had practiced in their groups. Each word was shown to the child and read by the instructor in a sounding out and blending fashion, as he or she ran his or her finger under the word: The word was said phoneme by phoneme with the sounds stretched and still connected to encourage the children to use decoding skills, yet not disrupting coarticulatory effects. The word was then repeated at a typical speaking rate. A sentence was also read that provided a meaningful context for the word. The child was then asked to say the word in a similar fashion while running his or her finger under it. This was repeated for all the 10 words. A recall trial was then completed in which the 10 words were shown individually and the child asked to read each one by sounding out the letters; if incorrect, the answer was given and the child asked to repeat the word out loud stretching the sounds while again running his or her finger under the word. Trials (i.e., attempts at reading all 10 words) were repeated with the word order varied randomly, until all the 10 words were read correctly on two consecutive trials (or to a maximum of five trials). Reliability was excellent ($\alpha = .94$).

Intervention

The study included one invented-spelling training group and two control groups. The first control group received an alternative phonological awareness training, whereas the second control group was asked to draw pictures for the target words. All children in each of the three groups were taught 13 letter – sound associations necessary to form the training target words as well as the pre- and posttest words. Letter – sound training was included for three reasons: (a) to avoid any constraint of low letter – sound knowledge on posttest measures, (b) to optimize learning in the phonological awareness comparison group (Ehri et al., 2001), and (c) to control for a possible confounding influence of increased exposure to letters in the invented-spelling group. Letter – sound teaching was carried out through a group activity, in which the children were taught a rhythmic chant for each letter, with a sequence of clapping and knee slapping, which gave both the name and the sound of the letter with simultaneous presentation of the printed letter. This activity occurred for approximately 3 min at the start of each group session, with four letter sounds practiced each session and recycled in the same order throughout the duration of the training program.

The same target words were used in each group, in the same order, and with the same frequency of exposure. As indicated previously, all target words used during training were composed from the limited set of 13 letters taught to all groups, as were all regular words in the spelling and reading assessments (pre- and posttests). These letters included a variety of articulatory manners: voiced and voiceless stops (B, P, D, T), liquids (L, R), a nasal (N), fricative (S), glide (Y), and four common vowels (A, E, I, and O). Both short and long vowel sounds were taught.

To control for a possible confound of familiarity with syllable/word forms used in training, all groups were exposed to the same words and at the same frequency (see subsequently). There were 20 regularly spelled words used in this training study, and all were made from the 13 letters also taught to each group. The words were chosen to represent different syllable structures and vowel sounds. All words are presented in the Appendix. Note that 5 of these 20 words were also used in reading and spelling posttests, thus allowing for an evaluation of word reading and invented spelling for practiced words, respectively.

Invented-spelling group. This group was trained to increase the sophistication of their naturally occurring invented spellings. The training words were presented, one at a time, in both picture form and orally by the instructor. Each word was spoken out loud by the instructor at a normal speech rate. It was then repeated in a stretched manner with exaggerated articulation but with no pausing between the phonemes. The instructor said the word a third time (at a normal speech rate) and the children were asked to repeat the word out loud in unison. The word was said a fourth time and the children instructed to each print the word in a provided notebook. Children were instructed to print the word how they thought it would look. They were repeatedly encouraged to do their best and told that their spellings did not have to be the same as an adult might write or even be the same as the spellings produced by the other children in their group.

After each word was printed, the instructor went around the table offering individually tailored feedback in which each invented spelling was contrasted with an instructor-generated invented spelling representative of a minimal increase in sophistication. This feedback was provided in the context of praising the child's invented spelling and then showing another way to write the word; the corrected form typically contained one additional phoneme represented as per the developmental progression outlined by Gentry and Gillet (1993). For example, a child who spelled *eel* as *ekxn* would be shown an instructor-generated spelling with one additional level of sophistication— in this example the correct final phoneme. The instructor would thus copy the child's spelling, replacing the last letter with a conventional representation of the final phoneme *(ekxl)*. A similar procedure was recently used successfully with Portuguese-speaking kindergarten children by Martins and Silva (2006). Following the fourth session, feedback also included drawing the children's attention to any extra letters within their invented spellings. This was done to coincide with the phonological awareness group's switch to phoneme counting, as well as to offer additional help to the weaker spellers by focusing their attention on the correspondence between sounds within a word and the letters in their spellings. In the example mentioned previously, the corrected feedback given to the child's *ekxn* was to add the final *l* and remove the unnecessary letters, yielding *el*. Note that the procedure of providing feedback in the form of a model with one additional element of complexity resulted in providing the conventional spelling only when the child's production was one element away from being (conventionally) correct. For example, *eel* was only provided as the corrected spelling if the child produced *el* on his or her own, here, the one additional level of sophistication is to go from the accurate phonetic spelling to the conventional form. Following the individualized feedback, children turned to a clean page in their notebooks, and the procedure was repeated using the same word. After the word had been spelled (and feedback given) twice, the procedure was repeated with the next word from the list. Within each session, 5 words were spelled (twice each); these words were repeated for two consecutive sessions, yielding the total of 20 words over eight sessions; the ninth and final session repeated 5 of these words.

Phonological awareness group. This group was taught to analyze words into smaller segments. Following the developmental progression of phonological awareness tasks proposed by Ehri et al. (2001) and previous research on analytic phonological awareness training with children of this age (Ball & Blachman, 1991; Tangel & Blachman, 1992), two segmentation-related tasks were taught. Also, following previous research showing greater effects when letter–sound instruction is paired with phonological awareness training (Ehri et al., 2001), each session started with letter–sound training for the targeted sounds. Children in this group were first taught to match pictures based on shared initial and final sounds, using the first 10 of the 20 training words (in picture form), in the same order and at the same frequency as in the invented-spelling group (i.e., 5 words per session, each repeated twice and used for two consecutive sessions). Each child was given a sheet with the appropriate picture along with three others. All pictures were named by the instructor in the same fashion as for the invented-spelling group: one time at a normal speech rate, one time with stretched speech, and two more times at a normal rate, with the children repeating the word out loud in unison once. Thus, the frequency and manner of exposure to the training stimuli were carefully controlled across groups. For each target word, the children were asked to circle the pictures that started or ended the same. The instructor then went around the table offering individually tailored corrective feedback, modeling the correct answer as necessary. Each trial was then repeated.

For the final 10 words (i.e., final five sessions), the children were taught a phonemic segmenting task based on Elkonin's (1973) original *say-it and move-it* activity. In this task, children learned to represent each sound within a word by stamping a marker, once for each phoneme in a word, into squares below a picture of that word. Again, the instructor said each word four times as before, and the procedure modeled as necessary. For each word, the children were asked to repeat the word out loud in unison and to make the appropriate number of stamps as they did so. Individually tailored feedback was given and the trial repeated.

Control group. This group of children received similar instructions as the invented-spelling group, except that instead of writing each word, they were asked to draw a picture. They too heard each word four times and said each word once in unison. Following completion of each drawing, the instructor provided positive feedback to each child and then the procedure was repeated using the same word (as in the other groups). Recall that children in this control group also received letter–sound training at the beginning of each session.

Procedure

Children received the assigned intervention in small groups. Group size depended on the logistics of the number of children participating from each school and ranged from 3 to 6 children. Interventions were delivered in nine sessions scheduled over a 4-week period midway through the senior kindergarten school year. Each session lasted approximately 25 min, with equivalent instructional time given to all groups and conditions.

Interventions were delivered by one of three highly experienced instructors, including a speech language pathologist with past experience delivering intervention programs to groups of children. The other instructors were a licensed classroom teacher and an experienced research assistant. To avoid potential instructor effects, each instructor taught two invented-spelling groups, two phonological awareness groups, and two control groups (Troia, 1999).

Posttesting was completed over two individual assessment sessions, completed within 7 days of the last intervention session. Children were posttested in pseudorandom order, such that the same number of children from each intervention condition was tested each day. Posttesting included the areas hypothesized to be influenced by the types of training proposed here: letter–sound knowledge, invented spelling, phonological awareness, orthographic awareness, word reading, and word learning. All children received the same order of tasks, arranged to make for two sessions of equal length with varying task demands and response requirements.

Results

Pretest Measures

Triads of children from the same class were matched on measures of invented spelling, phonological awareness, and letter–sound knowledge. A multivariate analysis of variance (ANOVA) confirmed that there were no statistically significant group differences on the set of these measures, Wilks's lambda = .94, $F(6, 128) = 0.73$, $p = .63$. Although not a matching variable, children were also pretested on orthographic awareness, and the groups did not differ on this measure either, $F(2, 66) = 0.92$, $p = .40$. As noted, the 69 participating children were all considered to have very little or no word reading skills as indexed by their performance on a word reading screening measure (i.e., reading 10 high-frequency words). Of these children, 39 (57%) were able to read one decodable word only, 16 (23%) were able to read one irregular word only, and the remainder (20%) could not read any of the words. The intervention groups did not differ in their pretested word reading, $F(2, 66) = 0.03$, $p = .97$. The descriptive statistics for all pretest measures are presented in Table 1.

Posttest Measures

All posttest measures were entered into a multivariate ANOVA. This between-group test was statistically significant, Wilks's lambda = .65, $F(12, 122) = 2.41$, $p < .01$. Performance between groups on individual measures was then analyzed in a series of univariate ANOVA, followed by two planned orthogonal contrasts (Helmert) to address the previously stated hypotheses. With the exception of the phonological awareness analyses, the first contrast compared the invented-spelling group against the two control groups and the second compared the two control groups to each other. These analyses are presented next, followed by the results of the learn-to-read task. All posttest means and univariate test statistics are presented in Table 2.

Letter–sound knowledge. ANOVAs conducted on children's knowledge of the 13 letter sounds taught revealed no statistically significant group difference, $F(2, 66) = 0.42$, $p = .66$. There was also no difference for knowledge of the entire set of 27 graphemes/digraphs tested, $F(2, 66) = 0.35$, $p = .70$.

Invented spelling. An ANOVA on the complete invented-spelling posttest revealed a statistically significant group difference, $F(2, 66) = 3.79$, $p < .05$, with a moderate effect size ($\eta^2 = .103$). Considering the pattern of results in Table 2, the invented-spelling group appears superior to the other two groups; in support of the present hypothesis, a planned orthogonal contrast confirmed the significance of this difference, $t(66) = 2.70$, $p < .01$, whereas the other planned contrast revealed no statistically significant difference between the phonological awareness and the drawing groups, $t(66) = 0.54$, $p = .59$. Note that the same pattern of significant results was found when the analyses were repeated separately for the five words that were practiced in the intervention as well as for the five words not practiced. The higher scores observed for the invented-spelling group thus reflect the increased sophistication in the self-generated

Table 1
Means (Standard Deviations) for Each Pretest Measure

	Training group		
Measure (maximum)	Invented spelling	Phoneme awareness	Drawing
Invented spelling (60)	24.47 (11.36)	24.48 (12.65)	23.83 (10.78)
Letter sounds (27)	16.74 (6.82)	17.00 (4.41)	16.48 (5.48)
Trained letter sounds (13)	8.87 (3.98)	9.22 (2.56)	9.35 (2.95)
Phonological awareness[a]	29.35 (3.67)	30.17 (4.00)	29.39 (3.65)
Awareness of double consonants (10)	4.87 (1.58)	5.00 (2.02)	4.39 (1.92)
Awareness of vowels (10)	5.01 (1.07)	4.61 (1.44)	5.17 (1.44)
Reading: regular words (5)	0.57 (0.51)	0.61 (0.50)	0.53 (0.52)
Reading: irregular words (5)	0.22 (0.42)	0.17 (0.39)	0.30 (0.47)

$^*p < .05$. $^{**}p < .01$.

spellings of these children, across all words. Qualitative analyses revealed an increase in their ability to match a word's phonology with appropriate (phonetically or conventionally) letter sequences. Children in the invented-spelling group also became more adept at reducing the number of unnecessary letters in their invented spellings, as they appeared to become more aware of the correspondence between the number of phonemes heard and the number of graphemes needed. This increased sophistication is reflected in the change evident in the mean spelling score (out of 6) from 2.45 pretest to 4.00 posttest for the invented-spelling group. On average, this reflects a change from representation of the first and/or the last sound of a word to representing all sounds within an item. There was also variability evident both within groups and across words. Importantly, many children demonstrated different levels of invented spelling (i.e., as seen in variability across words), reflecting a gradual process of refinement rather than discrete stages per se, making it difficult to classify children by spelling level.

Phonological awareness. The mean performance of each group on the phonological awareness posttest composite was entered into a separate ANOVA, which revealed a statistically significant group difference, $F(2, 66) = 4.07$, $p < .05$, with a moderate effect size ($\eta^2 = .110$). To evaluate the effectiveness of the phonological awareness training, the first planned contrast here compared the phonological awareness group to the drawing group. As suggested by Table 2, the phonological awareness group did perform significantly better than the drawing group on this posttest measure, $t(66) = 2.15$, $p < .05$. The second planned contrast addressed the question of whether there would be a difference between the phonological awareness and the invented-spelling groups: No statistically significant difference was found, $t(66) = 0.85$, $p = .40$.

Orthographic awareness: Permissible sequences. An ANOVA revealed no statistically significant group difference for awareness of consonant doubling, $F(2, 66) = 0.32$, $p = .73$, but there was a significant difference for awareness of vowel presence, $F(2, 66) = 3.79$, $p < .05$, with a moderate effect size ($\eta^2 = .103$). In accordance with the present hypotheses, planned contrasts confirmed that the invented-spelling group performed significantly better than the other two groups on the vowel presence task, $t(66) = 2.59$, $p < .01$, whereas there was no statistically significant difference between the phonological awareness and the control groups, $t(66) = 0.94$, $p = .35$. The discrepancy in the pattern of results between the two orthographic awareness tasks can be reconciled with the nature of the training stimuli: Only one training word (*ladder*) contained a consonant doubling, and therefore, the children were not exposed to doublings intensively enough to promote learning of a generalized orthographic rule. Conversely, those in the invented-spelling group appear to have developed an increased awareness of the importance of vowels in spelling.

Word reading. Five regular (decodable) words in the word reading measure were also included in the training. Using these words as a dependent measure in an ANOVA revealed a statistically significant between-group difference, $F(2, 66) = 5.52$, $p < .01$, with a moderate effect size ($\eta^2 = .143$). The invented-spelling group appears superior to both the comparison groups, and planned orthogonal contrasts confirmed the significance of this difference. The invented-spelling group was found to have higher scores relative to the other two groups, $t(66) = 3.32$, $p < .001$, whereas there was no statistically significant difference between the phonological awareness and the control groups, $t(66) = 0.00$, $p = 1.00$. Note, however, that no statistically significant group differences were found when reading for the set of 10 novel words was analyzed, $F(2, 66) = 0.23$, $p = .80$. Hence, the immediate invented-spelling benefits seem limited to words for which children have practiced and thus may be developing some level of orthographic representation for. Given the low levels of pretested reading skills and the short intervention period, immediate transfer (of reading facilitation) to untrained words was not evident.

Facilitative effects: A learn-to-read task. The central hypothesis guiding this research was that invented spelling helps kindergarten children integrate phonological and orthographic information into initial lexical representations that can facilitate reading acquisition. To test this hypothesis directly, children were administered a learn-to-read task at posttest. Mean group performance on each of the five word-association recall trials is depicted in Figure 1. As evident in this presentation, the invented-spelling group appears to have outperformed the other groups on all trials. This was confirmed through a repeated measures analysis, which revealed a statistically significant between-group difference on the series of trials as a set, $F(2, 66) = 3.92$, $p < .05$, with a moderate effect size ($\eta^2 = .106$). There was a main effect of trial, $F(4, 264) = 82.56$, $p < .001$, and no significant interaction between group and trial, $F(8, 264) < 1$, $p = .65$. Planned orthogonal contrasts (Helmert) on the total scores over the series of trials confirmed the observed superior performance of the invented-spelling group over the two comparison groups (contrast estimate = 1.59, $SE = 0.59$, $p < .01$), whereas there was no statistically significant difference between the phonological awareness and the control groups (contrast estimate = 0.08, $SE = 0.62$, $p = .90$). These results provide direct support for the hypothesized role of invented spelling in learning to read words.

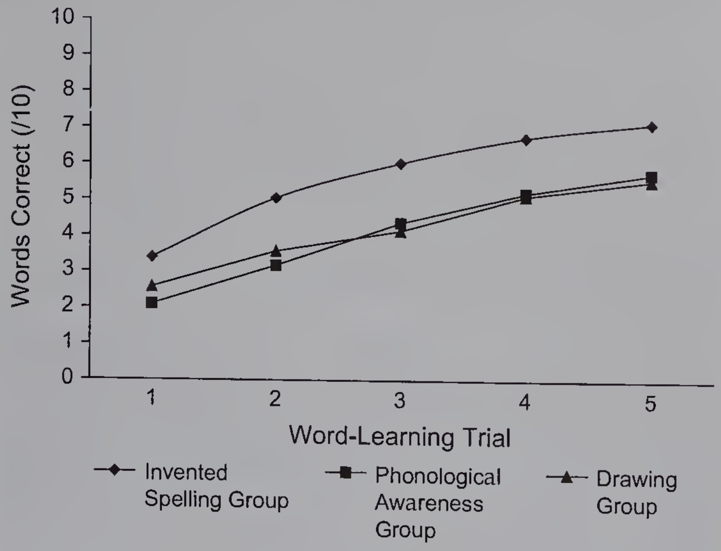

Figure 1. Mean number of words read on each trial of the learn-to-read task following completion of training.

Discussion

The findings of the present training study highlight the importance of invented spelling in the acquisition of early literacy skills and validate the training procedures used. Although all groups learned letter–sound knowledge, the invented-spelling group demonstrated more advanced invented spellings than did the other groups, and both the invented-spelling and the phonological awareness groups demonstrated superior phonological awareness. Invented-spelling training also benefited orthographic awareness and reading of words used in the training protocol.

Most importantly, the present results provide direct evidence for a causal role of invented spelling with developmentally appropriate feedback, in learning to read, thus confirming the hypotheses of Frith (1985) and Treiman (1993). In particular, the invented-spelling group learned to read more words in the learn-to-read task than did the children in the other groups. The present results offer direct training evidence that improvements in invented spelling can bring about an advantage in learning how to read. As previously discussed, invented spelling offers a powerful milieu in which to learn critical phonological awareness skills. Invented spelling, however, involves more than phonological awareness. It is important to note that in the present study, both the invented-spelling and the phonological awareness training brought about equivalent levels of posttested phonological awareness. Yet, the invented-spelling group was superior on the learn-to-read task. The present training results are thus interpreted as evidence that invented spelling coupled with feedback helps children hone and integrate a host of important skills that are potentially involved in learning how to read. In particular, invented spelling leads to increased phonological and orthographic awareness, and as proposed by Frith, invented spelling provides valuable insight and practice with the alphabetic code.

The exploratory nature of invented spelling encourages children to use an analytical approach that also promotes the integration of phonological and alphabetic information into initial lexical representations that connect phonological and orthographic information; as these lexical representations become refined, they may facilitate the acquisition of reading. This interpretation is congruent with the lexical quality hypothesis of Perfetti and Hart (2002) in that it highlights the importance of integrating information/representations from the domains of phonology and orthography. Invented spelling appears to provide children with an interactive activity to explore and analyze the written code and in the process make these proposed important associations between phonological and orthographic representations that will constitute the basis for complete lexical representations invoked in reading.

The invented-spelling group also outperformed the two control groups in reading the words used during training. Rieben et al. (2005) also reported superior reading for practiced words only for one of their invented-spelling training groups. This finding may be explained by the intensity of practice offered in the present study, along with the gradual developmental acquisition of lexical representations. In particular, the training involved spelling the same word more than once in a short time. This word-specific stimulation is more intensive than in typical child-directed spelling attempts, and this frequency of exposure may well be an important factor in learning to read words that were spelled. That is, with continued exposure and practice with the same word, the child is able to refine the respective lexical representation. This continuing refinement of representations is reflected in the described gradual, not stage-like, increases in spelling sophistication and eventual word reading skill seen within the invented-spelling training group.

In the present training study, the invented-spelling and phonological awareness groups had equivalent phonological awareness at posttest. Invented spelling with feedback, therefore, offers another context in which children learn valuable phonological awareness skills. This interpretation is consistent with Treiman (1993) and Mann et al. (1987), who proposed that invented spelling fosters phonological awareness growth, and is in accord with the recent training study reported by Martins and Silva (2006).

It should be noted that the invented-spelling training offered in the present study differed considerably from the combined phonological awareness and spelling training found in the phonological awareness intervention literature. That is, studies that combine word segmentation training with spelling (e.g., Uhry & Shepherd, 1993) explicitly teach phonological segmentation and then introduce letter tiles to directly combine phonological awareness and spelling. Children are then directly taught to spell words in the accepted conventional form. In the present invented-spelling training, however, there was no direct teaching of phonological segmentation and no explicit instruction bridging segmentation with conventional letter – sound mapping. Rather, children were encouraged to analyze and represent each word in their own way, followed by individualized feedback. The feedback was given to increase the phonological accuracy and complexity of children's spelling attempts. Specifically, the feedback respected the previously observed progression from initial nonalphabetic markings or random strings of letters to capturing the initial sounds of words, then marking the initial and final sounds, and then to the appearance of medial vowels in children's invented spellings (Gentry & Gillet, 1993). The progression also included the gradual elimination of extra letters. Martins and Silva (2006) successfully used similar feedback (i.e., provided models indicative of a higher phase of invented spelling) in their intervention research with Portuguese children. Although Portuguese is considered a much more transparent or shallow orthography than English, it too has inconsistencies in spelling (Defior, Martos, & Cary, 2002). In both the Martins and Silva training research and the present study, invented spelling along with developmentally appropriate feedback contributed to phonological awareness skills. These results, therefore, provide teachers with a valuable evidence-based alternative tool to promote phonological awareness. At the same time, future research should be conducted to evaluate the comparative benefits of different types of feedback, including the direct teaching of conventional spelling (see Rieben et al., 2005).

The invented-spelling training with feedback also increased children's implicit awareness of the orthographic rule in English that words must contain a vowel. Invented spelling can, therefore, offer a meaningful context from which children can become sensitive to orthographic rules and thus begin to store orthographic representations. These results are especially relevant, given recent contentions in the literature concerning when children learn orthographic information. Models such as the self-teaching theory of Share (1995, 1999) proposes that children must first decode to learn orthographic knowledge, whereas others have suggested that mere exposure to printed words may suffice (also see Caravolas, Kessler, Hulme, & Snowling, 2005; Wright & Ehri, 2007). The present findings suggest another route to the acquisition of orthographic knowledge, and that is through the exploration afforded by invented spelling.

Interestingly, the phonological awareness training group in the present research did not outperform the control group on measures of reading. This finding appears contradictory with the conclusions of the meta-analytic review by Ehri et al. (2001). Although the phonological awareness group in the present study did receive letter – sound training on the 13 sounds that composed the target words, the connection between the phonemes in the target words and their letter representations remained implicit. This type of implicit training has been used in previous research that has shown positive effects on reading (e.g., Byrne & Fielding-Barnsley, 1995), but it may be the case that in a short-term intervention like ours, the connection between phoneme segmentation or categorization and letter sounds must be made more explicit. For example, children in the classic study by Bradley and Bryant (1985) were taught with the help of plastic letters how common sounds across words were represented with letters. It remains to be tested, therefore, whether explicit instruction on using letters to segment words would be as beneficial to reading as would the invented-spelling intervention in the present study. We contend, however, that the knowledge afforded by invented spelling with feedback goes beyond that of explicit phonemic awareness training with letters. The work of Cunningham (1990) is helpful here. In her research on phonemic awareness training (without letters), she showed that training that highlighted the value and application of phonemic awareness produced greater effects than instruction that focused exclusively on the phonological awareness skills. In a similar vein, it is possible that invented spelling allows young kindergarten children to understand at a metacognitive level the function and value of letter-sound correspondences, which, in turn, further benefits their entry into reading. This possibility remains to be tested.

In the present 4-week training study, the invented-spelling group outperformed the comparison groups in learning how to decode words, reading familiar words, phonological awareness, and orthographic knowledge. Caution is warranted, however, because the magnitude of the between-group differences is modest. Still, the present short-term intervention does provide initial empirical support for the proposal originally brought forth by Chomsky (1971), and reiterated by Clarke (1988), that invented spelling can be incorporated into early literacy instruction. In particular, invented spelling combined with feedback that offers models just above the child's developmental level could be used by kindergarten teachers to promote growth in children's ability to capture spoken language in writing with their increasing knowledge of letters, as well as promote growth in phonological and orthographic awareness and, eventually, in learning to read words. It must be stressed that although the invented-spelling intervention has been described as *training* in the present study, the process is more accurately described as one of facilitation. That is, it must be stressed that by definition, invented spelling is a natural process (Burns & Richgels, 1989; Richgels, 1995). The intervention employed in the present study took advantage of each child's own spelling productions but then offered individualized feedback intended to guide the child to capture more completely the phonology of words, albeit in an unconventional manner. As noted previously, the feedback also focused the child's attention on unnecessary letters in their spellings. In addition to the inclusion of feedback, the present study worked with a relative small set of 13 letters, the words to be spelled were regular, and children were asked to spell each word four times. Teachers might consider using such strategies to optimize learning and facilitate their providing feedback to children in a classroom setting.

Implementation in kindergarten classrooms of invented spelling with developmentally appropriate feedback presupposes that teachers are familiar with the developmental trajectory of invented spelling. Whether teachers have this knowledge at present is uncertain. Nonetheless, teachers could acquire this knowledge as was shown with phonological awareness knowledge. Specifically, recent findings have shown that teachers who participated in workshops on how to implement explicit phonological awareness training in their kindergarten classrooms showed increased knowledge, changed their practices, and had children with greater literacy skills in Grade 1 compared to a control group of teachers and children (McCutchen et al., 2002). Most encouraging, the instructors in the present study reported informally that they found the developmental feedback intuitive and easy to implement.

With respect to further teaching applications, invented spelling had been criticized in the past as exposing children to erroneous orthography (Clarke, 1988). The feedback offered in the present study, however, and the general context of the training made it clear to the children that their spellings were not the same as an adult's. Invented spellings were, therefore, never reinforced as correct in a conventional sense. It should also be noted that Clarke (1988) found improved irregular word reading in Grade 1 classrooms where invented spelling was encouraged, and in the present research, invented-spelling training actually increased the children's orthographic awareness. Together then, these findings should go a long way in alleviating fears that encouraging invented spelling will impede acquisition of conventional spelling. Indeed, invented spelling offers a naturally occurring process that can be used as a springboard to facilitate phonological and orthographic awareness and, importantly, can help children along the pathway to learning how to read.

Coaching, Truth Induction, and Young Maltreated Children's False Allegations and False Denials

Thomas D. Lyon

University of California, Irvine

Victoria A. Talwar
McGill University

This study examined the effects of coaching (encouragement and rehearsal of false reports) and truth induction (a child-friendly version of the oath or general reassurance about the consequences of disclosure) on 4- to 7-year-old maltreated children's reports ($N = 198$). Children were questioned using free recall, repeated yes – no questions, and highly suggestive suppositional questions. Coaching impaired children's accuracy. For free-recall and repeated yes – no questions, the oath exhibited some positive effects, but this effect diminished in the face of highly suggestive questions. Reassurance had few positive effects and no ill effects. Neither age nor understanding of the meaning and negative consequences of lying consistently predicted accuracy. The results support the utility of truth induction in enhancing the accuracy of child witnesses' reports.

The extent to which children's dishonesty may be affected by adult influences is of considerable theoretical and practical interest. Theoretically, knowledge concerning how adults influence children of various ages provides insight into cognitive and social development. Practically, children are routinely questioned about alleged experiences, both in day-to-day situations in which parents, teachers, and others inquire into mostly mundane events, and in more serious settings, such as legal contexts, where children's statements can have far-reaching implications.

The purpose of the present study was to examine factors influencing dishonesty in a large sample of maltreated children, with a specific focus on how adult influences affect dishonesty. Maltreated children are particularly likely to be subjected to pressures to disclose or conceal information (Malloy, Lyon, & Quas, 2007; Sas & Cunningham, 1995), and their honesty and dishonesty are often at issue in legal contexts (Brennan, 1994), thus highlighting the need to understand dishonesty in this population. Moreover, two forms of dishonest behavior should be considered: false denials of true events and false allegations of untrue events.

Several factors are potentially important in influencing children's dishonesty. First, many of children's lies concern actions involving others (Wilson, Smith, & Ross, 2003), and others often seek to influence children's honesty. The latter person may be called an "instigator," to reflect his or her potential influence on children's statements. Efforts by instigators to encourage and rehearse dishonesty in children will be referred to here as "coaching." Second, the person to whom children lie, referred to as the "recipient," may also exert some influence. In an applied context, the recipient is often an interviewer, although a recipient could be any person with whom children interact. Third, several characteristics in children likely affect their dishonesty, including their age and attitudes about the morality and utility of dishonesty.

Portions of this research were presented at the 17th annual meeting of the American Psychological Society, Los Angeles, CA, 2005, and the annual meeting of the American Psychology & Law Society, La Jolla, CA, 2005. Esi Benyarku, Alan Kang, Vanessa Negrete, David Reinert, Lauren Threatte, and Christina Tsai assisted in data collection and coding. We are grateful for the support of the presiding judge of the Los Angeles County Juvenile Court, the Los Angeles County Department of Children's and Family Services, Los Angeles County Children's Law Center, the Children's Services Division of Los Angeles County Counsel, and the Los Angeles County Child Advocate's Office. Preparation of this article was supported in part by National Institute of Child and Human Development Grant HD047290-01A2 and National Science Foundation Grant BCS-0241586.

Research relevant to each of these factors will be considered in turn.

Instigator Behavior

Research on the influence of third persons on children's dishonesty has usually examined situations in which the instigator asks the child to conceal the instigator's wrongdoing, often resulting in high rates of false denial (Bottoms, Goodman, Schwartz-Kenney, & Thomas, 2002; Bussey & Grimbeek, 1995; Ceci & Leichtman, 1992; Pipe & Wilson, 1994; Talwar, Lee, Bala, & Lindsay, 2004; Wilson & Pipe, 1989). Some research has also demonstrated that instigators can successfully encourage children to make false allegations, both in situations in which children's motivation was to sustain a game (Quas, Davis, Goodman, & Myers, 2007; Tate, Warren, & Hess, 1992) and in situations in which children's motivation was to conceal a parent's wrongdoing (Tye, Amato, Honts, Devitt, & Peters, 1999).

An open question, and one we sought to explore, is whether instigator influence may be overcome, particularly in situations where children have been extensively coached to make false reports. This is a typical concern in maltreatment cases; the defense often argues that abuse allegations are the product of coaching (Brennan, 1994), whereas the prosecution argues that inconsistencies and retractions are themselves the product of instigator influence (Summit, 1983).

Recipient Behavior

Two lines of research are relevant to how the behavior of a recipient affects children's dishonesty. One concerns the types of questions asked by the recipient, and the other concerns the statements made by the recipient to promote honesty. With regard to question type, research investigating children's concealment of transgressions finds that yes–no and other direct questions are more effective in reducing false denials than open-ended questions (Bottoms et al., 2002; Pipe & Wilson, 1994). However, the former types of questions can also increase the likelihood of false allegations (Thompson, Clarke-Stewart, & Lepore, 1997). Moreover, children coached to make false allegations are more likely to do so in response to yes–no or forced-choice questions than in free recall (Quas et al., 2007). Hence, more direct questions may exert their influence not by eliciting greater honesty but by increasing acquiescence.

The recipient may also make explicit requests for honesty, an approach we refer to as truth induction. Truth induction is premised on the notion that children's dishonest behavior is in part determined by their perceptions of the consequences of honesty and dishonesty (Bandura, 1991; Bussey, 1992). For example, in the context of abuse disclosure, abuse victims often report that their decision regarding whether and when to disclose was affected by their expectations about how others would react to their disclosure and the effects of disclosure on themselves and others close to them (Anderson, Martin, Mullen, Romans, & Herbison, 1993). Furthermore, a primary motive for young children's lies is to avoid punishment for misdeeds (Bussey, 1992; DePaulo, Jordan, Irvine, & Laser, 1982; Ekman, 1989; Stouthamer-Loeber & Loeber, 1986). At the same time, at least by 5 years of age, most children exhibit good understanding that lying is itself punished (Bussey, 1992; Lyon & Saywitz, 1999; Peterson, Peterson, & Seeto, 1983). Hence, even at a young age, children appear to evaluate the consequences of their disclosures, and their evaluations in turn affect their behavior.

Two approaches to truth induction have been researched. The first involves the recipient highlighting the consequences of honesty and dishonesty. Some research has found that discussion of the morality of lying increases children's accuracy (Huffman, Warren, & Larson, 1999; London & Nunez, 2002; but see Talwar, Lee, Bala, & Lindsay, 2002). Other research has made children's obligations to be honest more explicit by eliciting a promise to tell the truth, analogous to the administration of the oath in court. Talwar et al. (2002, 2004) found that eliciting a promise from 3- to 11-year-olds to tell the truth decreased their tendency to deny falsely that they had peeked at a toy or that their parent had broken a toy. In a procedure similar to that employed here, Lyon and Dorado (in press) found that eliciting a promise decreased 5- to 7-year-old maltreated children's tendency to conceal their own and an adult instigator's transgression (play that the instigator had warned "might get [them] in trouble"). Moreover, the positive effects of the promise could not be attributed to acquiescence, because promising did not increase children's tendency to claim falsely that they had played, even when asked leading tag questions (e.g., "You opened some of the doors, didn't you?").

A second approach to truth induction involves reassurance, in which the recipient reassures the child that the recipient will not punish or otherwise react negatively to the child's disclosure of wrongdoing. Reassurance addresses the fact that, in some contexts, children may anticipate that honesty (rather than dishonesty) will be punished. To date, only one study has examined the potential for reassurance to decrease dishonesty. Lyon and Dorado (in press) provided maltreated children reassurance about disclosing forbidden play. The reassurance was specific in that the recipient explicitly mentioned the target play (i.e., "It's okay if you played with the toy house"). Specific reassurance decreased children's tendency to make false denials but increased false alarms among those children who exhibited some difficulty in understanding the meaning and negative consequences of lying. Hence, although some benefits of specific reassurance may exist, such reassurances also risk increasing acquiescence and false alarms (cf. Goodman, Batterman-Faunce, Schaaf, & Kenney, 2002).

No research has assessed whether reassurance decreases dishonesty without increasing false alarms if it is less specific, that is, if the recipient reassures the child without naming the wrongdoing in question.

In this study, we sought to examine the effects of eliciting a promise to tell the truth or general reassurance on children (referred to jointly as truth induction) while varying the question type from less to more leading (free recall, yes – no, and suppositional). In doing so, we sought to identify the optimal means to reduce dishonesty. In order to distinguish between honesty and acquiescence, we examined situations in which children were motivated to either falsely claim or falsely deny behavior.

Child Characteristics

Children's age and beliefs about the meaning and morality of dishonesty are potentially important in predicting dishonesty. First, the tendency to make false denials regarding transgressions emerges early in the preschool years and develops rapidly during this period, with substantial percentages of children as young as 3 years of age denying their own transgressions (Bussey, Lee, & Grimbeek, 1993; Lewis, Stanger, & Sullivan, 1989; Polak & Harris, 1999; Talwar, Gordon, & Lee, 2007; Talwar & Lee, 2002; Talwar et al., 2002). Similar age effects have been found regarding children's denial of transgressions of instigators who discouraged disclosure (Bottoms et al., 2002; Bussey & Grimbeek, 1995; Ceci & Leichtman, 1992). Relative to older children, 3-year-olds have a limited understanding of the effects of their statements on others' beliefs and are less aware of the negative consequences of revealing transgressions (Bottoms et al., 2002; Bussey & Grimbeek, 1995; Polak & Harris, 1999; Talwar & Lee, 2002; Tate et al., 1992). Moreover, younger children may find it more difficult to maintain a false story in light of the cognitive demands of monitoring one's responses for consistency and plausibility (Polak & Harris, 1999; Talwar & Lee, 2002; Talwar et al., 2007; Tate et al., 1992). Maltreated children, who tend to suffer from delays in development (Lyon & Saywitz, 1999; Shonk & Cicchetti, 2001), would likely exhibit similar patterns, albeit at somewhat later ages.

Second, children's understanding of the meaning and consequences of lying also develops during the preschool years (Bussey, 1992; Lyon & Saywitz, 1999; Peterson et al., 1983) and may have implications for their dishonesty. Although most research to date has not found an association between understanding and dishonesty (Feben, 1985; Goodman, Aman, & Hirschman, 1987; London & Nunez, 2002; Pipe & Wilson, 1994; Talwar et al., 2002), there are several reasons why a relation may have been missed. First, some research focused on memory errors rather than deliberately false statements (Feben, 1985; Goodman et al., 1987). Memory errors are not lies and therefore would be minimally influenced by a child's attitudes regarding honesty. Second, several studies examining the relation between children's understanding of lying and their tendency to deny a transgression had limited power to detect significant relations, either because of minimal variability in understanding (London & Nunez, 2002) or because understanding was measured with only a few questions (Pipe & Wilson, 1994; Talwar et al., 2002). Third, from a legal perspective, understanding of the meaning and morality of lying does not itself predict honesty but establishes an understanding of the oath. The supposition is that those who understand the oath are more likely to be influenced by the oath. Indeed, Talwar et al. (2004) found a positive relation between understanding of lying and honesty among children who had promised to tell the truth. Fourth, virtually all the research has examined possible relations between understanding and false denial of transgressions, without considering deliberately false allegations. Lyon and Dorado (in press) found that maltreated children who exhibited good understanding of the meaning and morality of the oath were less susceptible to making false allegations in response to leading tag questions than children who failed to exhibit good understanding.

Because of the potential effects of age on children's responsiveness to coaching and truth induction, we evaluated children across an age range during which one would expect developmental change in their abilities and proclivities to behave dishonestly. We also assessed children's attitudes about honesty and dishonesty in relation to coaching and truth induction to determine whether children's understanding predicted their behavior.

Present Study

In the present study, we examined the effects of instigator and recipient behavior on 4- to 7-year-old maltreated children's false allegations and false denials. During an initial phase, an instigator and a child either played or did not play with a toy house. Afterward, for half of the children, the instigator claimed that their behavior violated the recipient's expectations and provided extensive coaching so that the child would make a false report. That is, children who played were coached to deny that they had played, and children who did not play were coached to claim that they did. A recipient then interviewed the child about what happened and made increasingly strong suggestions that play with the house had occurred. The interview included free-recall, yes – no, and suppositional questions, which presupposed that play had occurred. During each phase of questioning, the recipient either gave no instructions (the control condition) or used one of the two types of truth induction. In the oath condition, children were asked to promise to tell the truth about what had occurred, and in the reassurance condition, children were reassured that disclosure of wrongdoing would not lead to punishment. The recipient also administered a task to assess children's understanding of the meaning of truth and lie and the negative consequences of lying. All procedures were approved by the researchers' institutional review boards as well as the presiding judge of the juvenile court and the agencies who work with maltreated children.

Based on prior research, three sets of hypotheses were tested. First, with respect to coaching, we predicted that dishonesty would be higher among coached children than among noncoached children, with respect to both children coached to make false denials and children coached to make false allegations. Second, with respect to truth induction, we predicted that the oath and reassurance would decrease dishonesty. We expected that reassurance would be particularly effective with respect to children who had played because of the likelihood that children would perceive such play as a transgression. However, reassurance should not increase false allegations among children who had not played because the form of reassurance used in this study did not explicitly mention play (in contrast to findings that specific reassurance increased false allegations among some children; Lyon & Dorado, in press). We further hypothesized that the efficacy of truth induction would depend upon the types of questions asked by the recipient, with induction least effective when coupled with the highly leading suppositional questions that presuppose play had occurred. Third, with respect to individual differences, we predicted that older children would be both more likely to lie and more likely influenced by truth induction than younger children and that greater understanding of the meaning and consequences of lying would be associated with more honest responding, at least in the truth induction conditions.

Method

Participants

Participants included one hundred and ninety-eight 4- to 7-year-old children (99 boys and 99 girls) who were awaiting a court appearance in the Los Angeles County Dependency Court. All children had been removed from the custody of their parent or guardian due to substantiated maltreatment. Children were ineligible to participate if they were Spanish speaking (either officially recognized as Spanish speaking by the court or clearly incapable of communicating with the researcher in English) or if they were awaiting an adjudication hearing on the day of their appearance in court (at which they might have to testify). The final sample included ninety-eight 4- to 5-year-olds (M = 63 months, range = 48 – 71 months) and one hundred 6- to 7-year-olds (M = 83 months, range = 72 – 95 months). Their ethnicity was diverse: Forty-four percent were Latino, 40% were African American, 10% were non-Hispanic Caucasian, and 6% were other or unknown.

Materials

Oath-taking competency task (Lyon & Saywitz, 1999). This task consists of questions about eight pictures, four regarding children's understanding of the meaning of "truth" and "lie" and four regarding children's understanding of the negative consequences of lying. For the meaning questions, pictures of two child characters looking at a single object are presented. One character labels the object correctly, and the other character labels the object incorrectly, with the labels depicted as pictures within talk bubbles. Children are asked which character "told the truth" (two trials) or "told a lie" (two trials), thereby assessing their understanding that truth refers to accurate statements and lie refers to inaccurate statements. For the consequence questions, pictures of two child characters talking to an adult (judge, doctor, social worker, or grandmother) are presented. One character is described as telling "the truth," and the other is described as telling "a lie." Children point to the character who "will get in trouble," with correct responses demonstrating children's understanding that lying has negative consequences. Correct responding to the meaning and consequence questions would qualify a child witness as competent to take the oath (and thus to testify; Lyon, 2000).

Toy house. A toy house was constructed out of Lego™ building blocks. The house had several small doors on each side, with small toys hidden behind each door. The house was placed on a revolving platform so that each side could be easily accessed.

Procedure

For ease of exposition, the recipient will be referred to as "she" and the instigator as "he." All recipients were female, and two of the four instigators were male; instigator–recipient pairs were equally distributed across the conditions. The recipient invited eligible children to participate in the study and obtained their assent. She then administered the oath-taking competency task and afterward told the child that she had to retrieve a forgotten form in her office. She asked the child to wait for her, and to help the child wait, she set a timer to 5 min and told the child that she would be back before the timer went off. Upon leaving, she gestured to the toy house on the floor and said that they would play with it when she returned.

Instigator–child interaction. Shortly after the recipient left, the instigator entered the room and introduced himself. He engaged the child in a guessing game with a coin, in which one person guessed in which fist the other person held a coin. During some of the trials, the instigator would hide the coin so that neither fist held the coin and remark, "It's fun to trick people." Next, the instigator engaged the child in one of the four conditions: play, play coach, no-play, or no-play coach. The instigator spent approximately 5 min with each child, leaving shortly before the timer rang.

In the *play* ($n = 52$) and *play coach* conditions ($n = 49$), after playing the guessing game, the instigator noticed the toy house, lifted it onto the table, and engaged the child in play with the toy. He ensured that both he and the child opened doors, looked at the toys inside, and took the toys out. He labeled his actions, explicitly encouraged the child to engage in each action, and labeled the child's actions, thereby making the interaction with the house and toys quite salient to the child.

In the play condition, the instigator continued to play with the child and the toy until it was time to return the toy to the floor. He then said good-bye and left. In the play coach condition, the instigator interrupted the play to coach the child to deny play. He said, "We might get in trouble if anyone finds out that we played with the toy. I need you to do something for me. When that lady comes back, she is going to ask you what we did. Don't tell her we played with the toy. She is going to ask you a bunch of questions about what we did in here. Tell her we played with the coin, but don't tell her about the house. I'll come back in a little while and tell her what happened. Can you help me, and trick her so she doesn't know we played with the toy?" Children who expressed reluctance were given additional encouragement to help. The instigator then practiced asking the child a few questions (both free recall and yes–no) to ensure that the child understood the instructions (e.g., "What did you do while I was gone?"). If the child disclosed that he or she played the guessing game in response to a practice question, the instigator responded with positive feedback. If the child reported playing with the house, the instigator instructed, "Try saying we played with the coin. Don't tell her we played with the house yet." Practice questions were delivered twice if the child gave the coached responses and thrice if the child did not follow the lead. As the instigator prepared to leave, he told the child, "Remember—tell her that we played with the coin, but please don't tell her about the toy. I'll tell her what happened later."

Children in the two no-play conditions did not engage in play with the toy house. In the *no-play* condition ($n = 49$), the instigator played the guessing game with the child the entire time he was in the room and never mentioned the toy house. In the *no-play coach* condition ($n = 48$), after playing the guessing game the instigator said, "Oh no! You know what, we were supposed to play with that toy on the floor! I need you to do something for me. When that lady comes back, she is going to ask you what we did. Let's tell her that we played with the toy." The instigator then followed a script that paralleled the play coach condition, except that he coached the child to claim that they had played with the toy house. The instigator explained that the toy house had doors with toys inside and practiced questions in which the child would falsely claim that they had touched the toy house, opened the doors, and taken toys out.

Recipient–child interview. When the recipient returned, she immediately asked a preinduction free-recall question, "What happened in here while I was gone?" followed by two "tell-me-more" prompts ("You said x. Tell me more about x.") Pilot testing revealed that children often blurted out their coached stories upon the recipient's arrival, making it impossible to deliver truth induction instructions. Therefore, we included this free-recall question, which enabled us to examine the influence of instigator coaching on children's reports prior to any truth induction.

Next, the recipient delivered one of the three truth induction instructions. In the *oath* condition ($n = 67$), the recipient said, "It's very important that you tell me the truth. Can you promise that you will tell me the truth? Will you tell me any lies?" (The latter question, which always elicited a "no" response, was asked to ensure that children were not simply acquiescing when answering "yes" to the first question.) In the *reassurance* condition ($n = 66$), the recipient said, "I talk to kids all the time about things that make them feel bad. If something happened that you feel bad or sad about, it's totally o.k. You won't get in any trouble with me at all. We can try to fix it and make it better." In the *control* condition ($n = 65$), the recipient gave no instructions. The recipient then asked the postinduction free-recall question ("Now, what happened in here while I was gone?") followed by two tell-me-more prompts.

The recipient then told the child, "I'm going to ask some more questions to make sure I have this right." Children in the oath condition were reminded, "Remember, you promised you would tell me the truth and that you won't tell me any lies." Children in the reassurance condition were reminded, "Remember you won't get in trouble with me for telling what happened."

The recipient then asked the repeated yes–no questions. The first two oriented the child to the instigator's activities: "While I was gone, did anyone come in the room?" and, if the child answered "yes," "Was it a man or a lady?" (the interviewer then used the appropriate pronoun for the remaining questions). If the child denied that anyone had come in the room, the interviewer omitted all subsequent yes–no questions about the instigator (and the child was scored as answering "no" to these questions). There were six yes–no questions about the child's and instigator's interaction with the toy house, with the order of asking about the instigator's and child's interaction counterbalanced. The questions were "While I was gone, did you [he] touch any of the doors?" "Did you [he] open any of the doors?" and "Did you [he] take any of the toys out?" Each question was immediately repeated in a skeptical tone.

The recipient then insisted that the child and instigator had played with the toy house, saying that he "comes in all the time and plays with my toys. I *know* that he came in and that *both* of you played with my toy house." The recipient repeated the truth induction instructions for children in the oath and reassurance conditions and then asked the six suppositional questions. These questions presupposed that the child and instigator had played with the house, and the order of the questions about the child and instigator was counterbalanced. The questions were "When you [the man] touched the doors, how many did you [he] touch?" "When you [the man] opened the doors, were you [was he] happy or mad?" and "When you [the man] took out the toys, did you [the man] play with them or look at them?"

To recap, there were four instigator conditions, two in which the child played with the toy house (play and play coach) and two in which the child did not (no-play and no-play coach). For each play or no-play condition, there was a corresponding condition in which the instigator coached the child to provide a false report. There were three truth induction conditions: control (no instructions), oath, and reassurance. The instigator and recipient conditions were fully crossed so that there were 12 groups and at least 16 children in each combination of instigator and recipient condition. All children were asked three types of questions: free recall, repeated yes–no, and suppositional.

Debriefing. The instigator then entered the room and fully disclosed what had happened while the recipient was away. The child was fully debriefed. Specifically, the recipient told the child that the instigator was her friend, that the 2 worked together at school, and that she knew the instigator would play with the child. She explained that the purpose of the study was to find the ways of helping children to tell the truth. She acknowledged that it is sometimes difficult to tell what happened but emphasized that it is important to tell the truth and thanked the child for helping.

Results

Children's interview responses were scored for three types of information: house and nonhouse free-recall details, accuracy to yes–no questions, and acquiescence to suppositional questions. For all scores, responses from 15% of the children (randomly selected across study conditions) were coded by two independent raters. Proportion agreement for free recall was 90%, and kappas for the other variables were $\geq .92$. Discrepancies were resolved through discussion. Preliminary analyses revealed no gender differences in performance or order (oath-taking competency task meaning stories first or consequence stories first, questions about instigator behavior first or child behavior first) effects. These factors are not considered further.

Free Recall

Children were asked recall questions twice, once before any truth induction and once after. Free-recall scores included the number of house and nonhouse details. House details were coded liberally and included any reference to the house that might be interpreted as play with the house (e.g., "I was playing with that [points to house on floor]"; "There are toys inside those [referring to windows on house]"). Nonhouse details referred to any other factual information provided by the child about their behavior while the recipient was absent (e.g., "We was playing the coin game"; "There was a lady"; "She had a penny"). Children's mean house and nonhouse details provided preinduction and postinduction are presented in Tables 1 and 2, respectively.

House details were correct for children who actually played with the house (i.e., children in the play and play coach conditions) but incorrect for children who did not play with the house (i.e., children in the no-play and no-play coach conditions). Depending on whether children had in fact played, both coaching and truth induction were expected to have opposite effects: Children who played would say less about play when coached to deny such play and more under truth induction, whereas children who did not play would say more about play when coached to do so and less under truth induction. Therefore, we assessed children's free recall separately for children who played and who did not play.

Table 1
Means (Standard Deviations) for Preinduction Free-Recall House and Nonhouse Details

	House	Nonhouse
Play (n = 52)		
4- to 5-year-olds	1.33 (1.55)	1.58 (1.28)
6- to 7-year-olds	1.93 (1.65)	2.46 (1.29)
M	1.65 (1.62)	2.06 (1.35)
Play coach (n = 49)		
4- to 5-year-olds	0.92 (1.82)	1.72 (1.31)
6- to 7-year-olds	0.54 (1.47)	1.67 (1.20)
M	0.74 (1.66)	1.69 (1.25)
No-play (n = 49)		
4- to 5-year-olds	0.04 (0.20)	2.38 (1.88)
6- to 7-year-olds	0.20 (0.71)	2.88 (1.09)
M	0.12 (0.53)	2.63 (1.54)
No-play coach (n = 46)		
4- to 5-year-olds	2.65 (2.35)	1.39 (1.31)
6- to 7-year-olds	4.26 (2.05)	1.04 (1.15)
M	3.46 (2.33)	1.22 (1.23)

Children's first recall (preinduction) performance reflected the influences of coaching and age before any truth induction. We conducted analyses of variance (ANOVAs) on the number of house and nonhouse details with age and instigator condition as between-subjects factors and type of detail (house vs. nonhouse) as a within-subjects factor. For children who played, significant main effects of instigator (play vs. play coach), $F(1, 97) = 9.93$, $p < .01$, partial $\eta^2 = .093$, and type of detail, $F(1, 97) = 9.74$, $p < .01$, partial $\eta^2 = .091$, emerged, as did a significant interaction between instigator and age, $F(1, 97) = 5.96$, $p = .01$, partial $\eta^2 = .058$. Children provided more nonhouse details (M = 1.88), than house details (M = 1.21). Also, although children provided fewer details in the play coach condition than in the play condition, this was qualified by the interaction with age. Older but not younger children produced fewer details when they were coached to deny play than when not coached, $t(97) = 2.85$, $p < .01$, $d = .98$, and among the children who played, older children provided more details than younger children, $t(97) = 1.85$, $p < .05$, $d = .67$. Summed house and nonhouse details are as follows: older play $M = 4.39$, play coach $M = 2.21$, younger play $M = 2.92$, and play coach $M = 2.64$.

The effects of coaching can also be examined by considering the number of children in each group who mentioned any play with the house. Because of the age differences for children in the play conditions, we analyzed the age groups separately. Although the younger children were only marginally less likely to disclose play when coached not to do so, 32% (8 of 25) in the play coach condition versus 58% (14 of 24) in the play condition, $\chi^2(3) = 3.43$, $p = .06$, $\varphi = .26$, the older children were clearly influenced by coaching: 27% (4 of 24) disclosed play in the play coach condition compared to 75% (21 of 28) in the play condition, $\chi^2(3) = 17.62$, $p < .001$, $\varphi = .58$.

Next, we examined preinduction performance among children who had not played with the house and hence for whom house details were false. If children in the no-play coach condition revealed the fact that the instigator had coached them to claim that they had played with the house (n = 2), they were coded as having provided zero house details because they were not reporting that they had actually played with the house. An ANOVA on the number of house and nonhouse details with age and instigator as between-subjects factors and type of detail as a within-subjects factor revealed significant main effects of age, $F(1, 93) = 5.98$, $p < .05$, partial $\eta^2 = .06$, and instigator, $F(1, 93) = 21.03$, $p < .001$, partial $\eta^2 = .19$,

4- to 5-year-olds	0.00 (0.00)	2.13 (1.81)	0.13 (0.35)	1.50 (1.20)	0.25 (0.71)	1.13 (1.25)
6- to 7-year-olds	0.11 (0.33)	1.67 (1.80)	0.00 (0.00)	1.63 (1.69)	0.00 (0.00)	2.50 (1.77)
M	0.06 (0.24)	1.88 (1.76)	0.06 (0.25)	1.56 (1.41)	0.13 (0.50)	1.81 (1.64)
No-play coach (n = 46)						
4- to 5-year-olds	2.25 (2.92)	0.13 (0.35)	0.43 (0.79)	1.29 (1.11)	1.25 (2.38)	1.13 (1.36)
6- to 7-year-olds	1.29 (1.38)	0.43 (0.79)	1.13 (2.23)	1.13 (0.99)	1.75 (2.38)	1.00 (1.07)
M	1.80 (2.31)	0.27 (0.59)	0.80 (1.70)	1.20 (1.01)	1.50 (2.31)	1.06 (1.18)

as well as a significant interaction between instigator and type of detail, $F(1, 93) = 92.75$, $p < .001$, partial $\eta^2 = .50$, and a three-way interaction among age, instigator, and type of detail, $F(1, 93) = 5.23$, $p < .05$, partial $\eta^2 = .05$. Older children ($M = 4.10$) provided more details overall than younger children ($M = 3.17$), and children coached to falsely claim play ($M = 4.54$) provided more details overall than children not coached ($M = 2.74$). The interaction between instigator and type of detail was attributable to the fact that coaching children to claim house play led to an increase in the number of house details (no-play coach $M = 3.31$ and no-play $M = 0.12$) and a decrease in the number of nonhouse details (no-play coach $M = 1.23$ and no-play $M = 2.63$), $ts(93) > 4.18$, $p < .001$, $ds > .90$. The three-way interaction was attributable to the fact that the increase in the number of house details relative to the number of nonhouse details in the no-play coach condition was larger among the older children.

Whereas both age groups in the no-play coach condition provided a comparable number of nonhouse details, older children provided a substantially larger amount of house details than younger children, $t(46) = 2.61$, $p < .05$, $d = .73$ (Table 1).

We were able to assess the effects of coaching among children who did not play by counting the number of children who mentioned play in their preinduction free recall. Coaching clearly increased their tendency to claim play with the house; 6% (3 of 49) did so in the no-play condition compared to 82% (39 of 48) in the no-play coach condition, $\chi^2(3) = 55.74$, $p < .001$, $\varphi = .75$.

Children's second recall reflected possible influences of truth induction in addition to coaching and age (Table 2). First, children who played with the house were considered. We conducted an ANOVA on the number of house and nonhouse details with age, instigator, and induction as between-subjects factors and type of detail as a within-subjects factor. A significant main effect of instigator, $F(1, 89) = 8.41$, $p < .001$, partial $\eta^2 = .09$, revealed that children in the play condition provided more details than children in the play coach condition ($Ms = 3.14$ and 1.82). A significant main effect of induction, $F(2, 89) = 4.03$, $p < .05$, partial $\eta^2 = .08$, showed that children provided more information when administered the oath ($M = 3.36$) than when provided no instructions ($M = 1.84$), $t(89) = 1.93$, $p < .05$, $d = .49$, and, to some extent, than when provided reassurances ($M = 2.24$), $t(89) = 1.46$, $p < .10$, $d = .44$. However, this main effect was qualified by a significant interaction between age and induction, $F(2, 89) = 3.09$, $p = .05$, partial $\eta^2 = .07$. The induction effects were only evident among the 4- and 5-year-olds (oath $M = 3.22$, control $M = 0.94$, reassurance $M = 2.75$), $F(2, 46) = 4.59$, $p < .05$, partial $\eta^2 = .17$: Younger children who received the oath provided more information than children who received control instructions, $t(46) = 2.03$, $p < .05$, $d = .81$, as did younger children who received reassurance, $t(46) = 1.63$, $p = .05$, $d = .71$. The 6- and

7-year-olds did not differ in the amount of information provided based on induction (oath $M = 3.54$, control $M = 2.75$, reassurance $M = 1.74$). With respect to children who did not play with the toy but were coached to say that they had (the no-play coach condition), children were excluded if they explicitly disclosed the trick preinduction ($n = 2$) and children who disclosed the trick postinduction had house detail scores set to zero ($n = 5$; 4 in the oath condition and 1 in the reassurance condition). An ANOVA on the number of house and nonhouse details with age, instigator, and induction as between-subjects factors and type of detail as a within-subjects factor yielded a significant effect due to type of detail, $F(1, 83) = 7.49$, $p < .01$, partial $\eta^2 = .083$, and an interaction between instigator and detail, $F(1, 83) = 25.63$, $p < .001$, partial $\eta^2 = .236$, such that coaching led children to provide an equal number of house and nonhouse details, whereas children who were not coached to make false claims provided more nonhouse details, $t(83) = 5.59$, $p < .001$, $d = 1.73$—no-play coach: house $M = 1.35$, nonhouse $M = 0.85$; no-play: house $M = 0.08$, nonhouse $M = 1.76$.

The effects of induction can also be assessed by calculating the proportion of children who were initially dishonest but behaved honestly postinduction. With respect to children who played with the toy, examination of the counts suggested that the oath had an effect on children coached to conceal house play, whereas reassurance had an effect on children who failed to disclose play without any coaching. That is, for children in the play coach group, 5 of 12 children (42%) in the oath group who initially said nothing about play revealed play postinduction, compared to 3 of 25 children (12%) in the control and reassurance groups, $\chi^2(3) = 6.93, p < .01, \varphi = .43$. For children in the play group, 7 of 8 children (88%) in the reassurance group who had not initially mentioned play did so postinduction, compared to 4 of 9 children (44%) in the control and oath groups, $\chi^2(3) = 3.44, p = .06, \varphi = .44$.

Summary. As expected, coaching reliably affected children's tendency to disclose play with the toy house, both when they were coached to deny play that actually occurred and when coached to allege play that had not occurred. Older children were more affected by coaching than younger children. The oath and reassurance increased younger children's willingness to acknowledge truthfully that they had played with the toy house. For children who had not played but had been coached to make false allegations, truth induction had no reliable effects on disclosure. Thus, truth induction had some positive effects on increasing true disclosures among the younger children and no negative effects on false allegations.

Repeated Yes–No Questions

Following the free-recall prompts, the interviewer reminded children of the appropriate truth induction instructions and asked a series of repeated yes–no questions asking about play with the toy house. Accuracy proportion scores were created separately for questions about the child's and the instigator's behavior. For children who played with the house, accuracy reflected true disclosures, and for children who had not played with the house, accuracy reflected true denials. Less than 1% of children's responses were "do not know" or unscorable (e.g., unintelligible), and these responses were not considered further. Analyses comparing children's response accuracy between each initial question and when it was repeated revealed no significant differences (both directly or in conjunction with children's age, instigator, or induction condition), all $Fs(1 \text{ or } 2, 174) < 1.65$, *ns*. In fact, very few children changed any of their responses across the repeated questions ($M = 0.04$). Hence, children's responses to the initial and repeated questions were combined to create overall accuracy scores. Means are presented in Table 3.

We conducted an ANOVA on the children's accuracy scores with age, instigator (play, play coach, no-play, and no-play coach), and induction as between-subjects factors and actor (child vs. instigator) as a within-subjects factor. A significant main effect of instigator, $F(3, 174) = 36.84$, $p < .001$, partial $\eta^2 = .39$, reflected the fact that children in the no-play condition ($M = 0.93$) were considerably more accurate in denying house play than all other children, including children who were coached to claim falsely that they had played ($M = 0.50$). Children in the play condition ($M = 0.60$) were more accurate in acknowledging play than children coached to deny play falsely ($M = 0.28$), $ts > 4.80$, $ps < .01$, $ds > .98$.

A significant main effect of induction, $F(2, 174) = 11.85$, $p < .001$, partial $\eta^2 = .12$, showed that children who were administered the oath answered a significantly greater proportion of questions correctly ($M = 0.72$), than did children administered no induction instructions ($M = 0.50$), or children provided reassurance ($M = 0.51$), $ts > 3.20$, $ps < .001$, $ds > .56$.

There was also a significant three-way interaction among actor, age, and instigator, $F(3, 174) = 3.28$, $p < .05$, partial $\eta^2 = .05$, which revealed that in the play condition (but in none of the other instigator conditions), age interacted with instigator, $F(1, 46) = 5.37$, $p < .05$, partial $\eta^2 = .10$. Examination of the means

(Table 3) reveals that whereas younger children were less accurate with respect to their own actions (hence less willing to acknowledge that they had played with the house), older children were less accurate with respect to the instigator's actions.

Summary. Coaching reliably affected children's tendency to disclose both true and false play when asked repeated yes–no questions. The oath consistently showed positive effects in terms of reducing false denials and false alarms. Reassurance had no effect. Of interest, question repetition did not affect children's accuracy and led very few children to change their responses. Age had virtually no effect on children's performance.

Suppositional Questions

The suppositional questions presupposed that the child and instigator had engaged in play and merely asked the child to clarify details of that interaction. The questions were highly leading and followed the recipient's insistence that the child and the instigator had played with the toy house. This component of the procedure was analogous to suggestibility studies that have elicited high rates of false allegations among young children (e.g., Thompson et al., 1997). We coded children's answers for whether they acquiesced to the presupposition that they had played with the house; acquiescence was scored as correct for children who had played with the house and incorrect for children who had not played with the house. Three percent of children's responses across the questions were either "do not know" or unscorable and were not considered further. Children's accuracy in response to the suppositional questions is presented in Table 4.

An ANOVA on children's accuracy scores with age, instigator, and induction as between-subjects factors and actor (child vs. instigator) as a within-subjects factor yielded significant effects due to age, $F(1, 174) = 7.86$, $p < .01$, partial $\eta^2 = .04$, and instigator, $F(1, 174) = 104.43$, $p < .001$, partial $\eta^2 = .64$. Younger children ($M = 0.53$) were less accurate than older children ($M = 0.64$); children who did not play with the toy house (and for whom the suppositional questions were misleading) were less accurate than children who did, and children who were coached were less accurate than children who were not coached: play $M = 0.92$, warn $M = 0.83$, no-play $M = 0.43$, no-play coach $M = 0.11$; all $ts > 4.21$, $ps < .001$, $ds > .56$.

However, a significant interaction between age and instigator, $F(3, 174) = 6.39$, partial $\eta^2 = .10$, showed that the age effect was limited to the no-play condition, $F(1, 47) = 13.27$, $p < .01$, partial $\eta^2 = .22$. When children neither played with the house nor were coached to claim they had, younger children were significantly less able to resist the questions presupposing house play ($M = 0.24$) than were the older children ($M = 0.62$). Age differences were nonsignificant for children in the other three instigator conditions.

An interaction between actor and instigator, $F(3, 174) = 9.10$, partial $\eta^2 = .14$, $ps < .01$, showed that in the absence of coaching, children were more willing to acquiesce to suggestions about the

confederate's play than about their own play. Differences were significant in the play and no-play conditions, $Fs(1, 51 \text{ and } 1, 48) > 7.22, ps \leq .01$, partial $\eta^2 = .12$ and $.23$, respectively, but not in the two coaching conditions. In the play condition, this meant that their accuracy was higher for the instigator's actions ($M = 0.99$) than for their own ($M = 0.91$) because acquiescence reflected accurate responding. Conversely, in the no-play condition, children's greater willingness to acquiesce to questions about the instigator meant that their accuracy was lower for the instigator's actions ($M = 0.35$) than for their own ($M = 0.51$) because acquiescence reduced accuracy.

Summary. The recipient's insistence that the child and confederate had played with the toy, coupled with highly leading questions presupposing that play had occurred, effectively led to very high rates of acquiescence. And, as expected, in the face of such strong suggestion, truth induction had no effects on children's accuracy. Children exhibited greater acquiescence to questions about the confederate's actions than about their own but only in the absence of coaching. We also observed age differences in accuracy but only in the absence of either coaching or play with the toy.

Relations Between Oath-Taking Competency and Performance

The final set of analyses examined whether children's accuracy was related to their performance on the oath-taking competency task, which included questions about children's understanding of both the meaning and the consequences of lying. The task was designed to assess children's basic understanding of the fact that truth and lie refer to factual and counterfactual statements, respectively, and that telling lies has negative consequences, which constitutes the minimum legal standard for qualification to take the oath (Lyon, 2000). Children passing such tasks might not fully appreciate distinctions among jokes, lies, and pretense, and might not have internalized standards against lying but would nevertheless believe that the oath required their best efforts to avoid falsehoods and that falsehoods would be subject to punishment. Children's performance on the two subtasks was significantly related, $r(198) = .42$, and because children would be expected to do well on both tasks in order to qualify to take the oath, we combined children's scores.

Correlations were computed between children's oath-taking competency scores and their free-recall, repeated yes–no question, and suppositional question performance. Because we predicted that the scores would predict performance specifically when children were given the oath (cf. Talwar et al., 2004), we analyzed the truth induction conditions separately. None of the correlations between children's competency scores and interview performance were significant among children in the reassurance and control conditions, $rs = -.05$ to $.11$, and $dfs = 59$ to 63. Among children in the oath condition, however, higher scores on the competency measure were associated with greater accuracy when answering the suppositional questions, $r(67) = .27, p < .05$ (both with respect to actions of the child, $r = .26$, and instigator, $r = .27$, $ps < .05$). Because children's competency performance was correlated with age, $r(198) = .40$, we recomputed the significant relations controlling for age; the correlation between children's competency scores and both their overall performance on the suppositional questions and suppositional questions regarding their own behavior remained significant, $rs(64) = .25$ and $.26$, $ps < .05$, respectively.

A legal perspective suggests an additional approach to analyzing the significance of children's competency scores. In court, competency is a dichotomous judgment such that children who fail to perform well on questions about the meaning and consequences of lying are found incompetent to take the oath and are not allowed to testify. Hence, it is worthwhile to consider if children who failed to perform at ceiling on the competency questions ($N = 61$) were less likely to be influenced by the oath than children who performed at ceiling ($N = 71$; examining children in the control and oath conditions). Hence, we entered children's performance on the oath-taking competency questions (at ceiling vs. not at ceiling) as a between-subjects variable in a series of ANOVAs examining postinduction recall scores, repeated yes–no question accuracy, and suppositional question accuracy. Competency did not emerge as a significant predictor of performance in any of the analyses, nor did competency interact with induction to affect children's performance. Instead, the same truth induction effects already reported reemerged, both among children who had and had not performed at ceiling on the competency measure. In other words, children who failed to pass the competency task were no less likely to be influenced by the oath.

Discussion

The purpose of this study was to examine several potentially critical factors that may influence dishonesty in maltreated children. Our particular focus concerned the role of two types of adult influence: an instigator who extensively coaches a false report and a recipient who asks increasingly suggestive questions with the aid of truth induction. We created a strong coaching manipulation in order to provide a rigorous test of the potential for truth induction to undo coached false reports. We assessed an age range that has been found to undergo substantial development in the proclivity to behave dishonestly and susceptibility to adult influence and tested children's attitudes about the meaning and consequences of lying as a possible correlate of dishonesty.

Instigator Behavior

The coaching was extensive. The instigator provided a rationale for the false story, practiced answering questions with the child, and for the children coached to deny play with the house, practiced a cover story. The recipient questioned the child immediately postcoaching, maximizing the likelihood that the child would remember the coaching and maintain the motivation to respond dishonestly. As predicted, coaching had consistent and robust effects on children's honesty, both when coached to claim that play had occurred and when coached to deny that play had occurred. That is, across analyses, the effect sizes routinely fell in the moderate to large range (Cohen, 1988).

Recipient Behavior

Despite the extensiveness and effectiveness of the coaching, the oath frequently led to improvements in children's performance. Whereas prior research has found that the oath increases children's honesty when they have been warned not to disclose transgressions (Lyon & Dorado, in press; Talwar et al., 2002, 2004), ours is the first to find that the oath increases accuracy among children extensively coached to either conceal or falsely reveal information. For children coached to deny play, the oath exhibited the most consistent positive effects, most of which were moderate in size, increasing disclosure among younger children in their free recall, and among both age groups in response to the repeated yes–no questions. For children coached to claim play falsely, the oath did not affect children's free-recall performance but led to greater accuracy in response to the repeated yes–no questions. Moreover, whereas prior research has found that specific reassurance in which the recipient explicitly mentions the target behavior can impair performance (Lyon & Dorado, in press), this study demonstrates that general reassurance exhibited no reliable tendency to increase false reports. At the same time, however there was only very limited evidence that reassurance improved the accuracy of children's reports.

Repeated yes–no questioning, often characterized as highly suggestive (Ceci & Friedman, 2000; Endres, Poggenpohl, & Erben, 1999), did not undermine truth induction's efficacy. Indeed, we were surprised to find that repeated questioning had no effect on children's accuracy, and very few children changed their responses. This was so despite the fact that the questions were repeated immediately and with a skeptical tone, thus maximizing their suggestiveness (Endres et al., 1999). It may be that children's certainty about what actually occurred undermined repetition's effect (Lyon, 2002).

Truth induction's benefits did diminish, however, in response to the highly leading suppositional questions. When the recipient insisted that play with the house had occurred and asked a series of questions that presupposed play, false reports were high, a common finding in the suggestibility literature (e.g., Bruck, Ceci, & Principe, 2006). Under these circumstances, neither the oath nor reassurance had any effect. The results thus suggest that administering the oath in conjunction with free-recall and yes – no questions improves young children's performance but that any benefits of truth induction may be overridden if highly leading questions are asked. Moreover, although the differences were not statistically significant, reassured children occasionally looked worse than children in the control group. This pattern is consistent with other research finding that normally benign interviewing techniques may be contraindicated if coupled with highly suggestive questioning (e.g., Bruck, Melnyk, & Ceci, 2000).

Child Characteristics

We found some support for our prediction that older children would be more affected by coaching, with respect to both concealing true play and claiming false play. However, these age differences did not appear in response to yes – no and suppositional questions. With respect to truth induction, on the other hand, there was virtually no evidence that age mattered; indeed, the one age difference was contrary to our prediction, in that younger children were more influenced than older children by truth induction in free recall. We had anticipated that younger children's limited appreciation of the consequences of disclosure and the morality of lying would lead them to be less responsive to truth induction, but there was little evidence that this was the case. Rather, the most consistent finding was that children in this age range were quite uniform in their susceptibility to recipient influence.

Finally, there were few significant (and no large) age differences in overall accuracy, even when one would expect age differences due to suggestibility among younger children. Younger children showed some tendency to initially provide less information overall, which is consistent with the difficulty they have in spontaneously producing information when asked for free recall. However, there were no age differences in accuracy in response to the repeated yes – no questions. Younger children showed a greater tendency to acquiesce to the highly suggestive suppositional questions than older children, a common finding in suggestibility research (Bruck et al., 2006), but this was true in only one of the four instigator conditions. The lack of age effects in accuracy might be attributable at least in part to the fact that because we were interested in honesty and dishonesty, we deliberately minimized memory errors by questioning children immediately after their interaction with the instigator. Had a longer delay taken place between the instigator's instructions and the recipient's questioning, age differences may have emerged.

We also predicted that children's understanding of the meaning and consequences of lying would be positively related to their honesty in the oath condition. There were indeed some significant correlations, although they were infrequent. Moreover, the additional analyses suggested by legal approaches to competency suggest that although the competency scores have some predictive value in assessing the accuracy of children sworn to tell the truth, a dichotomous yes – no judgment about competency based on children's performance is likely to exclude children from testifying who would nevertheless be influenced by the oath (cf. Talwar et al., 2002, who found evidence that a promise to tell the truth decreased dishonesty among children who would probably fail an oath-taking competency assessment).

Age differences might nevertheless emerge if the age range is increased. Of course, still younger children will at some point simply lack the necessary comprehension to be influenced by coaching or a promise to tell the truth. Older children might be less influenced by either coaching or truth induction, because their moral behavior is increasingly influenced by self-evaluation as opposed to external influences (Bandura, 1991). Moral self-evaluations undergo substantial development during the early grade school years. Bussey (1992, 1999) found that it was not until second grade that children anticipated more pride for telling the truth than for lying, and some of the research has found that older grade schoolchildren are less inclined than younger children to lie for a transgressing instigator (Bussey & Grimbeek, 1995; Pipe & Wilson, 1994; but see Talwar et al., 2004).

It will be necessary, in subsequent research, to better identify individual differences in children's response to truth induction. Those individual differences, in turn, will give us insight into the mechanism by which truth induction exerts its effect. For example, if older children are less influenced by truth induction and more influenced by internal moral standards, this suggests that truth induction affects children's perceptions of the costs and benefits of honesty. Future research should directly assess children's expectations about the consequences of nondisclosure and disclosure, dishonesty and honesty.

Limitations

Although the present study's results are provocative and highlight the potential value of truth induction in decreasing dishonesty among maltreated children, several limitations should be acknowledged. First, the experimental context necessarily limited the external validity of the study. On the one hand, child witnesses obviously face much more serious pressures about more serious transgressions. Maltreated children often fear quite severe consequences for disclosure (Anderson et al., 1993), which may be little affected by reassurances regarding the recipient's reactions. A promise to tell the truth might be taken more seriously in the real world, but it is still likely insufficient to overcome many pressures. On the other hand, it may be easier to motivate honesty in children questioned about more serious events, given children's desire to avoid harm to themselves or others. Both false allegations and false denials carry more serious consequences in the real world than in our research.

Second, a similar and equally serious problem with external validity is that both the instigator and the recipient in this study were virtual strangers to the participants. Of course, because our participants were maltreated children who had been removed from their parents' custody, we could not examine the power of parents as instigators or recipients in influencing children's dishonesty. Recent research on children's disclosure of sexual abuse, however, demonstrates quite clearly the potential influence of adults who are emotionally close to the child (Hershkowitz, Lanes, & Lamb, 2007; Malloy et al., 2007).

Third, children in the coaching conditions were not truly "lying" but "tricking" the recipient, a necessary modification given the ethical problems inherent in teaching children to lie. A trick is intended to deceive but is only a temporary lie, as manifested by the instigator's reassurance to the child that they would ultimately disclose what they had done. At the same time, the high rates of nondisclosure and denial of play among the children who received no coaching suggested that they intuited that play with the toy house constituted a transgression (however minor), and these children had no expectation that the truth would be revealed.

Future Directions

It may be possible to increase the efficacy of truth induction in reducing dishonesty. Reassurance might be made effective if the recipient reassures the child about the reactions of parties other than the recipient, although in the real world, such reassurances might be difficult to make with confidence. A combination of reassurance with a promise to tell the truth might also have benefits. The combination could be particularly effective if children who have been coached to lie might otherwise interpret reassurance as guaranteeing that a false story will not be punished. When coached false reports are a concern, truth induction might be coupled with inquiries about coaching itself. Those questions might be quite pointed ("Did the man tell you what to say?") or more general ("What did the man say to you?"). The recipient in this study only pursued the hypothesis that the child had engaged in play with the toy house, making it incumbent on the child to disclose coaching.

Further work can also elucidate the conditions under which instigators exert stronger or weaker effects. In this study, the instigator was himself a transgressor who engaged the child in the transgression (recall that the coached children were either told that they were supposed to play, in the no-play coach condition, or that they were not supposed to play, in the play coach condition). We deliberately chose this design to mimic situations in which children themselves feel implicated in adults' wrongdoing (a common dilemma for many sexually abused children; Anderson et al., 1993). However, whether the instigator is the same person as the potential wrongdoer and whether the child is herself implicated in the target behavior are important factors to manipulate in subsequent research.

It will also be important in future to directly compare maltreated and nonmaltreated children. Instigator and recipient influences may have differential effects depending on a child's maltreatment history. Maltreatment is likely to have negative effects on children's trust that adults will not cause them harm (Shields, Ryan, & Cicchetti, 2001), which could make them particularly susceptible to secrecy. At the same time, developmental delays might make them less proficient at lying. Direct comparisons will enable us to better understand the effects of maltreatment on children's attitudes and behavior, the mechanisms affecting children's dishonesty, and the implications of child witness research for actual practice.

Finally, truth induction should be attempted in the field. Our focus on maltreated children who both had and had not transgressed highlights the study's implications for forensic interviewers assessing the costs and benefits of various interviewing approaches. Children who testify are disproportionately those who have been substantiated as maltreated and whose honesty is subject to challenge. Before truth induction can safely be attempted in the field, where its ultimate utility will be determined, it was necessary to establish its effects on both true and false reports in a laboratory context, where the truth is known. It was also imperative to examine truth induction in precisely the population that will be the subject of its use in the field. This study lays important groundwork for continued research concerning truth induction in actual forensic interviews.

Genetic Influences on Activity Level in Early Childhood: Do Situations Matter?

Kimberly J. Saudino
Boston University

Jeffrey A. Zapfe
Acentech Inc.

Although genetic influences on individual differences in activity level (AL) are well documented, few studies have considered the etiology of AL from a contextual perspective. In the present study, cross-situational and context-specific genetic effects on individual differences in AL at age 2 were examined. The AL of 312 twin pairs (144 monozygotic and 168 dzygotic) was mechanically assessed with actigraphs in the home and in laboratory test and play situations. AL displayed significant genetic variance in all 3 situations. Moreover, actigraph scores significantly correlated across situations. Multivariate genetic model-fitting analyses found that the observed cross-situational continuity in AL was due entirely to genetic factors. Situational differences in AL arise from genetic, shared environmental, and nonshared environmental influences.

Activity level (AL) is a pivotal individual differences variable in infancy and early childhood. A core dimension of nearly every temperament theory, AL is a highly salient feature of child behavior that has been linked to various facets of child health and development. Twin studies of temperament in infancy and early childhood have yielded considerable evidence that AL is genetically influenced (e.g., Braungart, Plomin, DeFries & Fulker, 1992; Cyphers, Phillips, Fulker, & Mrazek, 1990; Saudino & Eaton, 1991, 1995; Saudino, Plomin, & DeFries, 1996; Stevenson & Fielding, 1985); however, this is only a first step in the understanding of the etiology of this important temperament dimension. There are many questions that remain unanswered. For example, although developmentalists frequently acknowledge the importance of contextual factors on temperament (e.g., Mangelsdorf, Schoppe, & Burr, 2000), short-term situational changes in AL have rarely been considered from a behavioral genetic perspective. Because temperament is viewed as being stable, questions of genetic and environmental contributions to situational change have largely been ignored by temperament researchers. However, different situations place different demands on the individual and elicit different behaviors.

Longitudinal studies of developmental changes in AL suggest that genetic factors contribute to stability, whereas change is due to environmental factors (Saudino & Cherny, 2001a; Saudino et al., 1996), but the factors that influence developmental change and short-term situational change need not be the same (Plomin & Nesselroade, 1990). Behavioral change across situations is generally assumed to be due to environmental differences; however, this is an empirical question. It is possible that genetic factors contribute to short-term change as the individual goes from situation to situation. That is, individual differences in responding to specific situations might be influenced by genetic effects (Phillips & Matheny, 1997).

There is little doubt that AL is influenced by situational factors. The types of toys available, the presence of peers, and the stressfulness, novelty, or restrictiveness of the situation can affect children's mean levels of AL (e.g., Eaton & Keats, 1982; Fagot & O'Brien, 1994; Pinto & Tryon, 1996). More specific to the question of individual differences and cross-situational consistency and change, there is also change in terms of one's ordinal position within the group. For example, observations of AL at home correlate only modestly with observations of AL in playgroup situations or at school (Fagot & O'Brien, 1994; Schaughency & Fagot, 1993). Similarly, correlations between mechanical measures of AL taken in free play and test settings tend to be low in both clinical and control samples (Barkley & Ullman, 1975). Thus, the child who is active in one situation is not necessarily active in another. If this is the case, there must be some difference in the genetic and/or

environmental influences on individual differences in AL across situations.

Detecting Genetic Influences on Situational Change

The etiology of cross-situational consistency and change in temperament can be explored by using multivariate genetic analyses that assess the extent to which genetic effects on a measure of temperament in one situation are shared with genetic effects on another measure of the same dimension in a different situation. *Cross-situational* genetic effects are genetic influences that overlap across different situations. Such situation-general genetic factors contribute to the stability of temperament across situations. *Contextual* genetic influences are genetic effects that are unique to a specific situation and, consequently, contribute to situational changes in temperament. For example, in the MacArthur Longitudinal Twin Study, multivariate genetic analyses have been used to examine the extent to which genetic effects on a measure of shyness in the laboratory overlap with shyness in the home environment (Cherny, Fulker, Corley, Plomin & DeFries, 1994; Cherny et al., 2001). Although shyness in the laboratory and home were only modestly correlated, there was substantial overlap between the genetic influences involved in both situations. This finding of cross-situational genetic effects for shyness in the laboratory and the home means that genetic factors contribute to the stability of shyness across the two situations. Indeed, the observed phenotypic correlation between the two measures of shyness was almost entirely due to overlapping genetic effects. In contrast, differences between shyness in the laboratory and in the home were due primarily to environmental factors, although there were some small contextual, or situationally specific, genetic influences on shyness in the home.

What is the role of genetic influences on situational change in AL? Although not well studied, prior research suggests that genetic factors may contribute to *both* cross-situational stability and situational change in AL. For example, multivariate genetic analyses of teacher and tester-rated temperament in the Colorado Adoption Project found that although teacher and tester ratings of AL at age 7 were only modestly correlated (r = .19), there was substantial genetic overlap between the two measures (Schmitz, Saudino, Plomin, Fulker, & DeFries, 1996). Forty-six percent of the genetic variance in tester ratings was shared with teacher ratings. Moreover, only genetic factors contributed significantly to the covariance between teacher and tester ratings, indicating that what teachers and testers see in common in children's AL is due to genetic influences. Despite this evidence of cross-situational genetic effects, there was also significant genetic influence unique to tester ratings, indicating context-specific genetic effects for activity (i.e., 54% of the genetic variance on tester ratings was independent of genetic variance on teacher ratings). Similar results have emerged from an application of a multitrait–multimethod approach to infant twin data comprising three temperament dimensions (activity, emotional tone, and sociability) assessed three different ways (tester rating, playroom observation, and parent rating) that found substantial context-specific genetic variance in addition to cross-situational genetic variance (Phillips & Matheny, 1997).

These two studies are a first step in exploring genetic and environmental contributions to short-term situational change; however, in both studies, situational variance is confounded with method variance. For example, in the Schmitz et al. (1996) study, the informants differed across situation (i.e., the test and school situations). Similarly, in the Phillips and Matheny (1997) study, both informants *and* measures differed across the three situations. Research has clearly shown that for ratings of temperament and/or behavior problems, different informants typically do not contribute the same information about the child's behavior (Achenbach, McConaughy, & Howell, 1987; Mangelsdorf et al., 2000). Therefore, the confounding of situational and method variance in these studies limits conclusions regarding cross-situational consistency and change because it is difficult to say whether the context-specific genetic variance refers to true situational change or method differences.

Disentangling situational variance from method variance. To understand true situational change, we must disentangle situational variance from method variance. To do this, it is necessary to assess the behavior of interest with the *same* measure across different situations. For some dimensions of temperament (e.g., emotionality), this is difficult because different informants are often needed for different situations (e.g., home and school). This, however, is not a problem with AL because AL can be mechanically assessed across a variety of situations.

Despite the advantages of mechanical measures of AL, only one prior study has used mechanical motion recorders to explore situational effects in the etiology of individual differences in AL. A sample of school-aged twins wore motion recorders in a laboratory cognitive testing situation and during a 25-min break in testing (Wood et al., 2007). AL in the two situations was substantially correlated (r = .52), and AL was significantly heritable in both situations (h^2 test = .24, h^2 break = .30). In contrast to prior work suggesting contextual or situationally specific genetic effects (i.e., Phillips & Matheny, 1997; Schmitz et al., 1996), the genetic correlation between the two situations was estimated as 1.0, indicating complete overlap between the genetic influences operating on the two situations. At question, however, is whether the two laboratory situations were sufficiently different to reasonably expect that they would have different genetic etiologies. That is, more diverse situations may produce different results.

In the present study, cross-situational and context-specific genetic effects on individual differences in AL at age 2 were examined using mechanical motion recorders to assess AL in the home as well as in the laboratory. Twins wore motion recorders for 2 days in their homes, thus providing a naturalistic measure of AL. In addition, two laboratory-based measures of AL were obtained: one taken during a standardized test situation and another based on the child's behavior in a series of play-based activity episodes. Although the testing situation is a limited context in which to observe children's behavior, it is a standard situation that facilitates comparisons among children. Moreover, the somewhat stressful nature of the test situation enriches observations of certain temperament-like behaviors. In contrast, the laboratory play situation allows us to evaluate behaviors that may be more typical of children's day-to-day activity. Play situation episodes are standard across children, but activity within each episode is directed by the child. Thus, the present study explores situationally specific genetic effects in the home and in the laboratory situations and between the laboratory test and the play situations. Although we made no specific predictions about differential heritability across situations, it was predicted that AL would be genetically influenced in each of the three situations. Further, based on prior research and temperament theory, it was hypothesized that cross-situational continuity would be largely due to genetic factors (i.e., genetic influences contribute to the phenotypic correlation between situations). Nonetheless, given that laboratory measures of AL are typically modestly correlated with AL in the home, it was also predicted that there would be some context-specific genetic effects.

Method

Sample

The Boston University Twin Project sample was recruited from birth records supplied by the Massachusetts Registry of Vital Records. Twins were selected preferentially for higher birth weight and gestational age. No twins with birth weights less than 1,750 g or with gestational ages less than 34 weeks were included in the study. Twins were also excluded if one or both twins had a health problem that might affect motor activity (e.g., cerebral palsy, club foot) or had chromosomal abnormalities. The present analyses include 312 same-sex pairs of twins (144 monozygotic [MZ] and 168 dzygotic [DZ]), mean age 2.07 years (*SD* = 0.05). Although the sample was predominately Caucasian (85.4%), ethnicity was generally representative of the Massachusetts population (3.2% Black, 2% Asian, 7.3% mixed, and 2.2% other). Socioeconomic status according to the Hollingshead (1975), four-factor index ranged from low to upper middle class (range = 20.5 – 66; *M* = 50.9, *SD* = 14.1).

Zygosity was determined via DNA analyses using DNA obtained from cheek swab samples. In the cases where DNA was not available (*n* = 3), zygosity was determined using parents' responses on physical similarity questionnaires, which have been shown to be more than 95% accurate when compared to DNA markers (Price, Freeman, Craig, Ebersole, & Plomin, 2000). In our present sample, we were able to assign zygosity with certainty to 99% of the twin pairs using the parent questionnaire; moreover, agreement between questionnaire and DNA zygosity analyses was very high (κ = .94).

Procedure Overview

The twins were assessed within approximately 2 weeks of their second birthday. The procedure consisted of two visits, 48 hr apart, to the laboratory. At the initial visit, the motion recorders were attached to each child. After attachment of the motion recorders, one twin was assessed within a standardized test situation while the other twin was assessed within the laboratory play situation (both described subsequently). The second visit was scheduled for 48 hr following the attachment of the motion recorders. At this visit, the situations were reversed for each twin. Motion recorders were then removed, and the record sheets and cheek scrapings collected. Twins were assessed by different testers; however, for each twin, the tester was the same across the two laboratory situations. In the present study, the term *home situation* refers to all time spent outside the laboratory.

Test situation. The administration of the mental scale of *Bayley Scales of Infant Development – Second Edition* (Bayley, 1993) was used to provide a structured test situation for assessing AL. Assessment of AL during administration of the Bayley mental scale has been widely used in behavioral genetic research, but prior research has relied solely on observer ratings within this context (e.g., Braungart et al. 1992; Matheny, 1980, 1983; Saudino et al., 1996).

Play situation. Activity episodes from the *Laboratory Temperament Assessment Battery – Preschool Version* (Lab – TAB; Goldsmith, Reilly, Lemery, Longley, & Prescott, 1995) were used to provide standard play situations for assessing AL. Four Lab – TAB activity episodes were included in the present study: Corral of Balls: the child plays in a corral enclosure filled with many brightly colored balls (3 min); Arc of Toys: the child is presented with a variety of age-appropriate toys and is permitted to play with whatever toys he or she chooses (5 min); Workbench: in this measure of fine motor activity, the child is shown a work bench toy and is permitted to play with it (3 min); and Fidgeting Video: the child is seated in a child chair in front of a television monitor and shown an age-appropriate video (4 min).

Measures

Mechanical assessment of AL. During the 2-day data collection period, AL was assessed with the Mini Mitter actical (actigraph). This device is a miniature omnidirectional accelerometer that has been designed to detect frequency and intensity of motion within the range of normal human movement (Mini Mitter Company, 2005). Actigraphs have been shown to be valid and reliable instruments for recording the activity of children (Freedson et al., 1997; Janz, 1994). Each twin was randomly assigned four actigraphs, one per limb. Actigraphs were attached by means of Tyvek adhesive wristbands. Arm attachment, at the wrist, was on the dorsal aspect of the forearm proximal to the radial carpal joint. Leg attachment, at the ankles, was superior to the lateral malleoli.

Parents were provided with instructions regarding the care of the motion recorders and a sheet for logging the times when the actigraphs were off a limb. To differentiate actigraphs within twin pair, each actigraph was covered with white surgical tape on which the child's name was printed. Actigraphs were also color coded and keyed to a parent record sheet indicating the color of actigraph that went on each limb. Thus, the parent was able to easily identify the set of actigraphs that belongs to each twin and, further, to match the instrument to the correct limb. Parents were encouraged to engage in normal activities and to maintain daily routines with their children during the 2-day data collection period. The average length of time that the motion recorders were worn was 48.22 hr ($SD = 3.22$).

To adjust for variations in the total time that each instrument was worn within the home and lab situations, the number of activity units was converted to a rate per minute real time. Similar adjustments were made to the data from the test and play situations. Arm and leg activity counts were highly correlated ($r = .69$, $p < .001$); therefore, composite actigraph scores reflecting overall motor activity for each situation were calculated by averaging the four limb actigraph scores. Aggregating across motion recorders has been shown to increase both the reliability and the validity of AL measures (e.g., Eaton, 1983; Melanson & Freedson, 1995). Consistent with prior research, actigraph scores were positively skewed (Saudino & Eaton, 1991, 1995; Wood et al., 2007) and were square root transformed to create a more normal distribution.

Correlational Analyses

Twin intraclass correlations indexing co-twin similarity were calculated using the double-entry method. Because twin correlations can be inflated by variance due to gender, all scores were residualized for gender effects (McGue & Bouchard, 1984). These residualized scores were used in all behavioral genetic analyses. To evaluate genetic and environmental influences to cross-situational continuity, cross-twin cross-situation correlations were calculated. Cross-twin correlations are the essence of a multivariate analysis of covariance. For the present analyses, the cross-twin cross-situation correlation involved correlating the score of Twin 1 for AL in one situation with score of Twin 2 for AL in another and vice versa. Genetic contributions to the covariance between two measures are implied when the MZ cross-twin correlation is greater than the DZ cross-twin correlation.

Model-Fitting Analyses

Although the major results of a multivariate twin analysis can be gleaned from twin cross-correlations, model-fitting procedures analyze all the data simultaneously, provide tests of the fit of models, yield confidence intervals for parameter estimates, and tests the fit of alternative models (Plomin, DeFries, McClearn, & McGuffin, 2001). Models were fit to raw data using a maximum likelihood pedigree approach implemented in Mx structural equation modeling software (Neale, Boker, Xie, & Maes, 2006). This approach does not yield a chi-square statistic for assessing the fit of the model; however, the fit of a model can be assessed by calculating twice the difference between the negative log likelihood (−2LL) of the model and that of a saturated model (i.e., a model in which the variance–covariance structure is not estimated and all variances and covariances for MZ and DZ twins are estimated). The difference in −2LL is asymptotically distributed as a chi-square statistic with degrees of freedom equal to the difference in the number of parameters in the full model and that in the saturated model.

We fit two multivariate models to the data to examine cross-situational and contextual genetic effects on mechanically assessed AL. Both models decompose the phenotypic variance of each situation and the phenotypic covariances *between* situations into additive genetic effects (A), shared environmental effects (C), and nonshared environmental effects (E); however, each model makes different assumptions about the reasons for consistency across situations. In both models, additive genetic influences refer to the sum of the average effect of all genes that influence a trait. Based on the degree of genetic relatedness, the A factors correlate 1.0 and .5 for MZ and DZ twins, respectively. The C factors refer to the influence of shared rearing environments on twin resemblance. Because all twins were reared in the same family, shared environments correlate 1.0 for both MZ and DZ twins. Finally, the E factors reflect nonshared environmental influences that are unique to each member of a twin pair, including measurement error.

Independent pathway model. The independent pathway model (Kendler, Heath, Martin, & Eaves, 1987) assumes that genetic and environmental factors contribute to covariance between situations through separate genetic and environmental pathways. This model decomposes the genetic, shared environmental, and nonshared environmental variance of AL in the home, test situation, and play situations into genetic and environmental effects that are common to all three measures (i.e., cross-situational effects) and genetic and environmental effects that are unique to each situation (i.e., contextual effects). For example, in Figure 1, the latent variables A, C, and E represent additive genetic, shared environmental, and nonshared environmental effects, respectively, that are common to all three situations. The latent variables denoted in subscripted lowercase represent genetic and environmental effects on AL that are unique to a specific situation (e.g., a_h, c_h, and e_h refer to genetic and environmental influences unique to the home situation). Under this model, covariance between situations can arise due to different factors. That is, although measures of AL may be intercorrelated across all situations, the sources of covariance between any two situations may differ (e.g., the correlation between home and test situations could have a different source than the correlation between the test and the play situations). This model is considered to be "agnostic" in that it does not specify that the same phenotype operates across different situations; rather, it just allows that the phenotypes being assessed in each situation are correlated (Hewitt, Silberg, Neale, Eaves, & Erikson, 1992).

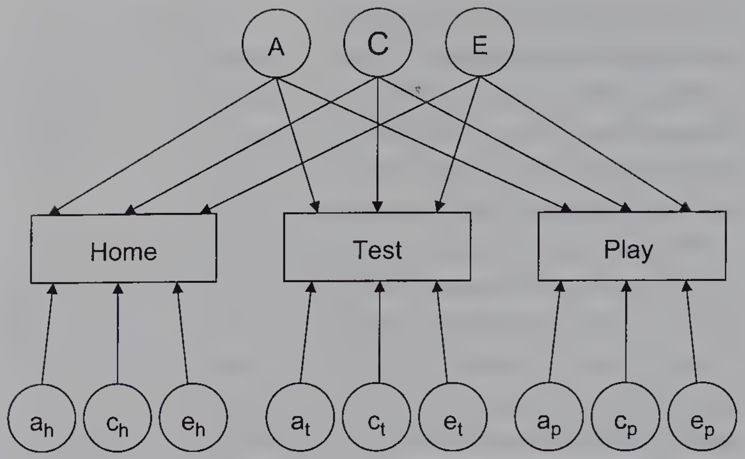

Figure 1. Independent pathway model.

Common pathway model. As compared to the independent pathway model, the common pathway model (Kendler et al., 1987; McArdle, & Goldsmith, 1990) is more restrictive positing that genetic and environmental factors influence covariation between situations through a *single* common pathway. This model suggests that correlations between situations arise because a common phenotype (AL in Figure 2) operates across all situations. This common phenotype is then influenced by genetic and environmental influences. As is the case for the independent pathway model, this model also allows genetic and environmental effects specific to each situation. Under this model, genetic and environmental sources of covariance are the same across all situations. Cross-situational consistency arises because different situations tap the same latent phenotype (i.e., they are assessing the same behaviors). Differences between situations arise because, to some extent, different contexts also evoke different phenotypes.

Results

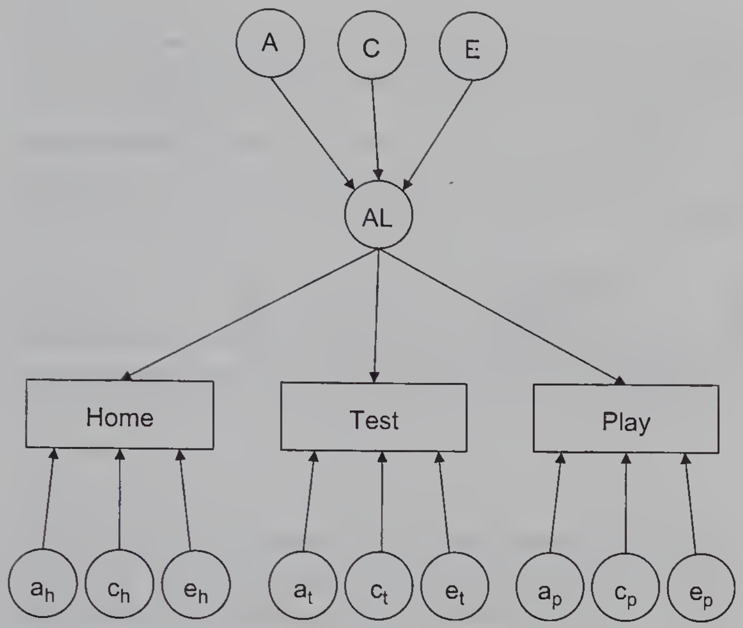

Figure 2. Common pathway model.

using generalized estimating equations (GEE) implemented in the SAS GENMOD procedure to account for dependence in the data due to the fact that our sample comprised pairs of twins. GEE are an extension of the standard generalized linear models that allow modeling of correlated data (Liang & Zeger, 1986; Zeger & Liang, 1986). Consistent with previous research on mechanically assessed AL (Saudino & Eaton, 1991, 1995), males were significantly more active that females (home: $z = -2.32$, $p < .05$; test: $z = -5.27$, $p < .001$; and play: $z = -4.08$, $p < .001$). The effect sizes as estimated by Cohen's *d* (Cohen, 1988) ranged from .24 to .48, indicating that the means for males and females differed by approximately one quarter to one half of a standard deviation. These effect sizes are comparable to those reported in meta-analyses of sex differences in temperament (Eaton & Enns, 1986; Else-Quest, Shibley Hyde, Goldsmith, & Van Hulle, 2006). More important to our twin analyses, MZ and DZ twins did not significantly differ in AL (home: $z = -.74$, $p = .46$; test: $z = -.68$, $p = .50$; and play: $z = .46$, $p = .65$).

AL Agreement Across Situations

Phenotypic correlations revealed substantial consistency in AL across the test and play situations ($r = .53$, $p < .001$). However, AL in the two laboratory situations were more modestly associated with AL at home (test: $r = .34$, $p < .001$ and play: $r = .33$, $p < .001$).

Twin Correlations

Twin intraclass correlations and cross-twin cross-situation correlations are presented in Table 2. For all three situations, the intraclass correlations for MZ twins exceeded those for DZ twins, suggesting genetic influences on AL. The very high intraclass correlations for both MZ and DZ twins in the home situation are particularly noteworthy and suggest that shared environmental influences also contribute to cotwin resemblance in this situation. Cross-twin cross-situation correlations for MZ twins were consistently higher that those for DZ twins, indicating that genetic factors contribute to the phenotypic correlation between AL across all three situations.

Model-Fitting Analyses

Univariate genetic analyses of AL in each situation (available from the first author) indicated that AL was significantly heritable in all three situations, suggesting that it is reasonable to inquire as to the extent to which there are cross-situational genetic effects (i.e., multivariate genetic analyses are warranted). Table 3 presents the fit statistics for the multivariate model-fitting analyses. As indicated by the nonsignificant

Table 1
Means (SD) for Activity Level by Sex and Zygosity in Home and Lab Situations

	Males		Females		Effect size	
Situation	MZ	DZ	MZ	DZ	Sex	Zygosity
Home	21.63 (2.49)	21.21 (2.45)	20.79 (2.45)	20.85 (2.10)	.24	.07
Test	24.71 (5.17)	24.37 (4.78)	22.35 (4.48)	22.08 (4.10)	.48	.05
Play	28.75 (7.24)	29.48 (6.53)	26.63 (6.81)	26.45 (6.86)	.38	−.05
n	146	182	142	154		

Note. Effect size estimated as Cohen's *d* expresses group differences in *SD* units. DZ = dzygotic twins; MZ = monozygotic twins.

Note. Intraclass correlations are given in bold on the diagonal. Cross-twin correlations are given below the diagonal. DZ = dizygotic twins; MZ = monozygotic twins.

chi-square statistics for the overall fit of the model, both multivariate models adequately describe the data. Because the common pathway model is nested within the independent pathway model, it is possible to determine the relative fit of the two models by comparing the difference in chi-square statistics between the two models. As can be seen, imposing the more restrictive common pathway model to the data did not result in a significant decrement in the fit of the model ($\Delta\chi^2 = 1.589$, $df = 4$, $p = .811$). Moreover, its considerably lower Akaike's information criterion (difference = 6.411) provides substantial evidence for the common pathway model as the best-fitting overall model. We were able to further simplify the common pathway model by dropping all paths that were nonsignficant in the full model. The reduced model included additive genetic variance (A) on the latent AL phenotype; unique genetic, shared, and nonshared environmental effects on the home; and unique nonshared environmental effects on the test and play situations.

Figure 3 presents the path estimates from the full and reduced common pathway models. Post hoc power analyses indicated that we had more than 98% power to detect significant genetic covariance, but power to detect common shared environmental and nonshared environmental influences was lower, 23% and 39%, respectively. Therefore, although we present the results for both full and reduced models, to avoid artificial inflation of parameter estimates, we focus on the parameter estimates from the full model (i.e., in reduced models, nonsignificant shared environmental variance is absorbed into genetic variance). The path estimates are standardized partial regressions indicating the relative influence of the latent variables on the phenotypes. The square of these path coefficient estimates represent the proportion of variance for each measure accounted for by the latent variable. For example, the heritability of the latent AL phenotype is $.84^2$. The total genetic variance for AL in the home situation is the heritability of the latent AL factor times the variance in the AL measure that is due to the common factor (i.e., square of the factor loading) plus unique genetic variance (i.e., $[.84^2 \times .44^2] + .40^2 = .30$). Variance components from both models are presented in Table 4.

Table 3
Fit Statistics for Multivariate Models of Activity Level in the Home, Test, and Play Situations

	Overall fit of model[a]						Relative fit of model		
	−2LL	*df*	χ^2	*df*	*p*	AIC	$\Delta\chi^2$	*df*	*p*

No common C or E and no unique a or c on test or play	**9,997.04**	**1,847**	**29.52**	**34**	**.69**	**−38.49**	3.96[c]	6	.68

Note. Best-fitting models are indicated in bold. AIC = Akaike's information criterion; χ^2 = chi-square fit statistic; −2LL = log-likelihood statistic.
[a] Overall fit of the model is determined by the difference in −2LL of the model and that of a saturated model.
[b] χ^2 difference between the independent pathway model and the common pathway model.
[c] χ^2 difference between the full common pathway model and the reduced model.

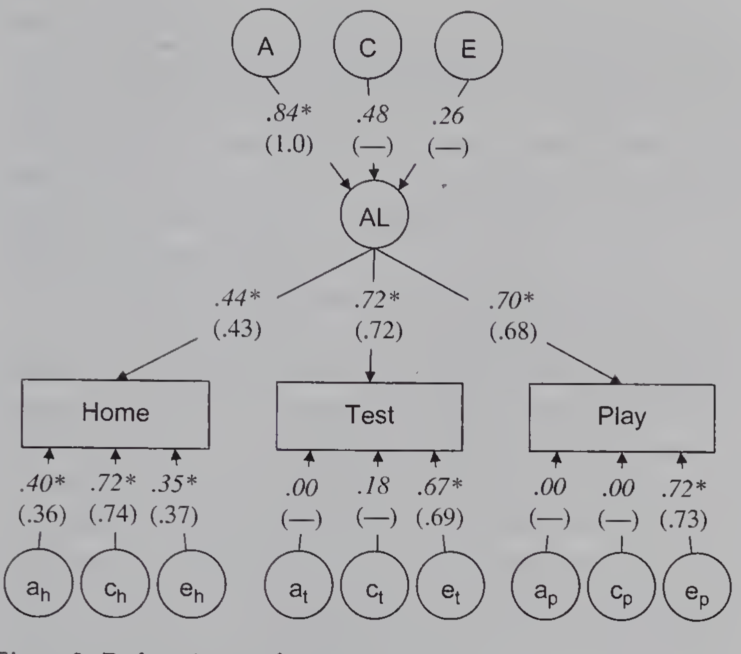

Figure 3. Path estimates from common pathway model.
Note. Estimates for the full model are given in italics. Asterisks indicate that the path was significant ($p < .05$) in the full model. Estimates for best-fitting reduced model are given in parentheses. Dashes indicate that the parameter was not included in the best-fitting reduced model. All paths in the reduced model are significant at $p < .05$.

Total variance components. AL was significantly heritable in all three situations, with genetic effects accounting for approximately one third of the total variance. As suggested by the twin intraclass correlations, AL in the home displayed significant and substantial shared environmental variance (i.e., more than 50% of the total variance). This pattern did not, however, emerge for AL in the laboratory. The environments that influenced AL in the test and play situations were of the nonshared variety.

Our multivariate model allowed us to test whether estimates of genetic and environmental variances significantly differed across situation. We fit models constraining either the genetic, shared environmental, or nonshared environmental variances to be equal across situations. These models were then compared to the full model. A significant change in chi-square statistic between models indicates that the constrained model provides a poorer fit to the data. It was possible to equate genetic variances ($\Delta\chi^2 = 0.636$, $df = 4$, $p = .96$), but neither the shared environmental variances ($\Delta\chi^2 = 20.418$, $df = 4$, $p < .001$) nor the nonshared environmental variances ($\Delta\chi^2 = 78.172$, $df = 4$, $p < .001$) could be equated across situations. Similar results emerged when genetic variances ($\Delta\chi^2 = 6.048$, $df = 4$, $p = .20$) or nonshared environmental variances ($\Delta\chi^2 = 88.672$, $df = 4$, $p < .001$) were equated in the reduced models. As indicated by the nonoverlapping confidence intervals, shared environmental variance was significantly higher and nonshared environmental variance significantly lower in the home situation as compared to AL in the lab.

Sources of covariance between situations. The significant factor loadings on the common latent AL factor indicate that the home, test, and play situations tap a common AL phenotype. This common AL factor explained 40% (i.e., $[.44^2 + .72^2 + .70^2]/3 = .40$) of the variance in our AL measures. Variation in the common AL phenotype is due to genetic influences (70%), neither shared nor nonshared environmental influences significantly influenced this common factor. In other words, covariance between situations (i.e., cross-situational consistency) arises because of common genetic influences. Genetic correlations indicating the extent to which genetic effects on AL in one situation correlate with genetic effects on AL in another situation, *independent of the heritability of each measure,* were substantial. The genetic effects on AL in the home correlated .68 (95% CI = 0.43 – 0.92) with AL in both laboratory situations. Similarly, the genetic correlation between AL in the test and in the play situations was 1.0 (95% CI = 0.78 – 1.0).

Cross-situational and situation-specific variance components. The genetic, shared, and nonshared environmental variances for each AL measure were decomposed into effects common across situations and those that are unique to a situation (Table 4). Approximately 50% of the genetic variance on AL in the home is situation specific (i.e., 16/30 = 53%). Neither AL in the test nor in the play situations displayed any unique genetic variance. Only AL in the home situation displayed significant shared environmental variance, accounting for more than 50% of the total variance on this measure; not surprising then was the finding of significant situation-specific shared environmental effects for the AL home measure. The only effects that were unique to the test and play situations were nonshared environmental influences, which include child-specific effects and measurement error.

Discussion

Do situations matter? There are two ways in which behavioral genetics research can approach this question. First, does the magnitude of genetic and environmental influence on AL differ across context or setting? A second, and perhaps less obvious, question involves the extent to which there is overlap

Table 4

Multivariate Estimates of Genetic and Environmental Variance (95% CI) From the Common Pathway Model

between the genetic and the environmental effects on AL in the home and two laboratory situations. This latter approach addresses the issue of genetic and environmental influences to cross-situational consistency and context-specific effects. In the paragraphs below we will discuss situational effects from both perspectives.

As would be predicted from temperament theory, AL in all three situations was genetically influenced. There was little evidence of differential heritability across situation. Situational differences were, however, apparent in the nature and magnitude of environmental influences. AL in the home environment was substantially influenced by shared environmental factors (explaining 56% of the variance). This was not the case for AL in the laboratory test or play situations that displayed no significant shared environmental variance.

The finding of significant and substantial shared environmental variance on AL in the home is particularly interesting given that this finding does not emerge when parent ratings are used to assess AL (e.g., Goldsmith, Buss & Lemery, 1997; Neale & Stevenson, 1989; Saudino & Cherny, 2001b). Nonetheless, prior studies that have used mechanical measures to assess AL in the home environment have hinted at shared environmental influences. For example, Plomin and Foch (1980) used a weeklong pedometer measure to assess the AL of twins in middle childhood. Genetic influences on individual differences in AL were significant; however, the very high correlations between MZ and DZ twins suggested that shared environmental influences were substantial (MZ: r = .99, DZ: r = .94). Similarly, actometer-based studies of infants, toddlers, and adolescents have suggested possible shared environmental influences on AL, but these early studies were limited by very small sample sizes (Saudino & Eaton, 1991, 1995; Saudino, Thompson, & Gagne, 2000). The present findings provide the strongest evidence to date for shared environmental influences on mechanically assessed AL. The failure for parent ratings to display shared environmental influences likely arises from rater contrast biases, which magnify existing behavioral differences between cotwins. Indeed, when contrast biases have been included in behavioral genetic models of parent-rated AL, significant shared environmental effects have emerged (Saudino, Cherny, & Plomin, 2000; Saudino, McGuire, Reiss, Hetherington, & Plomin, 1995).

What shared environments might be contributing to variability in AL in the home? There are several possibilities. Family practices and schedules (e.g., meal times, bed times, family outings, and caretakers' tolerances for AL) are a likely source of common variance between cotwins. It is also possible that the increased shared environmental variance in the home situation reflects twin-specific environments. For example, the twins playing together and sharing toys may contribute to resemblance in AL. However, there are three lines of evidence that suggest that our finding of shared environmental influences on AL in the home is not simply a twin effect. First, MZ and DZ twins did not significantly differ in variances for home AL, suggesting that that shared environmental variance is not a result of cooperative sibling interaction effects. Second, for a subsample of families (n = 144), we asked parents to complete an activity diary listing the approximate amount of times that the twins engaged in common activities (e.g., storytime, preschool). In this subsample, the pattern of very high MZ and DZ twin resemblances (e.g., MZ: r = .83, DZ: r = .65) and significant shared environmental effects remained after residualizing home AL scores for time spent in common twin activities. Finally, a previous study of nontwin siblings also showed substantial resemblance for a 48-hr measure of actigraph AL (Saudino, Wertz, Gagne, & Chawla, 2004). The reported correlation for nontwin siblings in this earlier study (.58) does not significantly differ from our correlation for DZ twins and when compared to the MZ twin correlation also suggests shared environmental influences. This is particularly noteworthy because the nontwin siblings differed in age by approximately 3 years and because there were subtle methodological differences across the two studies. For example, children in the sibling study wore only two actigraphs (which reduces the reliability of the AL measure and would attenuate the sibling correlation) and the AL measure included time spent in the lab (which could also attenuate the nontwin sibling correlation). Thus, although we cannot definitively rule out twin-specific environments, it would appear that our finding of shared environmental influences in the home is not merely a twin-specific effect.

Whatever the source of these shared environmental effects, they do not have an enduring influence across situation. That is, although there are family-wide factors that influence AL in the home, they do not influence AL outside the home. As indicated previously, shared environmental influences did not significantly contribute to AL in either the laboratory test or the play situations. Moreover, our multivariate modeling clearly indicated that the shared environmental variance on AL in the home was situation specific.

The home and laboratory situations also differed in the magnitude of nonshared environmental influences operating on AL. In the home, nonshared environmental influences were modest, explaining less than 15% of the variance in AL. In contrast, approximately 50% of the variance in the two laboratory situations was due to nonshared environmental influences. In all cases, nonshared environmental influences were situation specific. Nonshared environmental variance comprises those environmental factors that are unique to each member of a twin pair and that make twins different from each other. This includes measurement error; however, given that the same devices were worn continuously across the 48-hr data collection period, differences in the magnitude of nonshared environmental variance across situation cannot be simply attributed to measurement error. One possible source of nonshared environmental variance in the two laboratory situations was the tester. Although testers followed standardized protocols in the test and play situations, tester personality, behavioral standards, and even mood may have influenced their interactions with the children tested. Additionally, twins were tested in the same situations on different days, which may also have contributed to nonshared environmental variance specific to each situation.

The fact that the magnitude of heritability of AL is similar across all three situations does not mean that the same genes operate in each situation. That is, it is possible that AL in each situation could represent a genetically influenced, but etiologically distinct, phenotype. This does not appear to be the case. Multivariate genetic analyses indicate that the covariation between AL in the home, test, and play situations was best described by a common latent factor, suggesting that to some extent, the same AL phenotype was assessed in all situations. Individual differences in this underlying AL phenotype were due only to genetic influences, indicating that what is common across all situations is genetic. Neither shared nor nonshared environmental influences contributed significantly to cross-situational consistency in AL.

Genetic correlations across situation indicate that approximately 68% of the genetic factors that influence AL in the home also influence AL in the laboratory test and play situations and that the genetic influences in the two laboratory situations are completely overlapping. This finding of substantial genetic overlap between AL across situations is accordant with prior research that finds that cross-situational consistency arises because of common genetic influences (i.e., Phillips & Matheny, 1997; Schmitz et al., 1996; Wood et al., 2007); however, our actigraph methodology and inclusion of the home situation adds more resolution. As with Wood et al., (2007) we found a genetic correlation of 1.0 between actigraph-assessed AL in two distinct laboratory situations (test and play in our study and test and break in the Wood et al., 2007, study). Phillips and Matheny (1997) report a genetic correlation of .59 between AL in the laboratory play and in the test situations, but as indicated earlier, they used different methods to assess AL across the two situations, which likely contributed to the lower genetic correlation. We suggest that when methodology is consistent across situations, AL within standard laboratory situations is not genetically distinct. This is not necessarily the case for AL beyond the laboratory. Although there was considerable overlap between AL in the home and in the laboratory, there were genetic influences unique to the home situation. Approximately 50% of the genetic variance on AL in the home was situation specific (i.e., independent of genetic variance on the common AL phenotype) indicating context-specific genetic effects for AL. Unlike prior research (Phillips & Matheny, 1997; Schmitz et al., 1996), our finding of contextual or situational-specific genetic effects is not confounded by method effects. Thus, genetic factors contribute to both cross-situational consistency *and* situational change. Environmental influences, however, contribute only to situational change.

The present results are consistent with temperament theory that predicts that individual differences in AL are genetically influenced and show some consistency across situations (Goldsmith et al., 1987). Our genetically sensitive design paired with actigraph methodology allowed us to examine the source of this consistency across situations and to evaluate sources of short-term situational change. The findings support both a cross-situational and a contextual view of the genetic underpinnings of temperament. Consistency in AL across situations is due to common genetic influences. However, even though genetic factors are solely responsible for cross-situational continuity, there is also evidence of situationally specific genetic effects on AL in the home. Our interpretation of these situation-specific effects is that different contexts provide different views of AL and thus engage different genetic influences on processes relevant to each context.

The limitations of this study should be acknowledged. Our sample of just more than 300 twin pairs is relatively small. Although we had ample power to detect significant genetic variance and covariance, our power to detect shared environmental effects on AL was more variable (ranging from approximately

20% in the lab to more than 90% in the home). For this reason, we highlight the results from the full model as reduced models that set nonsignificant nonzero parameters to zero can bias estimates. Similarly, very large samples are required to detect significant differences in heritabilities across measures; therefore, our sample does not provide a powerful test of differential heritability across situations. We would note, however, that the magnitudes of heritabilities across situations were very similar, ranging from .30 to .37 in the full model, and even in the reduced model where the range was greater, the 95% confidence intervals were overlapping. Despite the limitations imposed by our sample size, the present study makes a unique contribution to the developmental literature. Most studies of genetic influences on AL have relied on parent-rating measures or brief behavioral observations, few have considered situational effects. Our 48-hr actigraph measure of AL across three situations provides a novel and rigorous test of situational effects on AL from a behavioral genetic perspective.

In conclusion, although what is common among AL assessed in the three situations is largely genetic, situations do matter—provided that the situations are sufficiently different. Although the two standard lab conditions displayed no shared variance beyond the common genetic variance, the more diverse home environment revealed additional shared variance (both genetic and environmental) in AL. These results have important implications for molecular genetics research seeking to find specific genes associated with AL. The fact that to some extent, different genetic influences operate on AL across different situations means that researchers will need to consider the situation in which AL is assessed. Failures to replicate molecular genetic findings may be due to situational differences between studies. This would be especially true when comparing results across lab and nonlab situations. Molecular genetic studies of AL may benefit from a multisituation approach, which would allow identification of genes that are associated with the common AL phenotype (i.e., cross-situational genes). That is, given that the AL common factor was highly heritable, the search for cross-situational genes may increase the power of molecular genetic studies of AL.

Stability and Change in Ethnic Labeling Among Adolescents From Asian and Latin American Immigrant Families

Andrew J. Fuligni
University of California, Los Angeles

Lisa Kiang
Wake Forest University

Melissa R. Witkow
Willamette University

Oscar Baldelomar
University of California, Los Angeles

An important question for the acculturation of adolescents from immigrant families is whether they retain ethnic labels that refer to their national origin (e.g., Mexican, Chinese) or adopt labels that are dominant in American society (e.g., Latino, Asian American, American). Approximately 380 adolescents from Asian and Latin American immigrant families selected ethnic labels during each of the 4 years of high school (age span = 14.87 – 17.82 years). Results indicated no normative trend either toward or away from identifying most closely with pan-ethnic or American ethnic labels. Significant numbers of adolescents changed their ethnic labels from year to year, however and these changes were associated with fluctuations in adolescents' ethnic affirmation and exploration and proficiency in their heritage languages.

Given the social importance and functional significance of ethnicity in American society, children are virtually required to figure out the ethnic and social categories into which they are placed. This task can be particularly challenging for children and adolescents from immigrant families who are less familiar with the ethnic categories and labels that are used in the United States. An important question for the acculturation of adolescents from immigrant families, therefore, is whether they retain ethnic labels that refer to their national origin (e.g., Mexican, Chinese) or move toward the adoption of labels that are dominant in American society (e.g., Latino, Asian American, American). Given that immigrant families comprise the large majority of those with Asian and Latin American backgrounds and that these are the two fastest rising ethnic groups in the United States, the answer to this question will have implications for the nature of ethnic categories and the development of ethnic identity in the broader society.

Ethnic Labeling Among Immigrants

An important aspect of identity development during the adolescent years is the process by which teenagers explore how they fit into existing social categories and groups (Ruble et al., 2004). Ethnicity is a meaningful and salient social category within the United States, differentiating people across an array of social, economic, and behavioral indicators. The process of ethnic identity development is particularly significant for those from ethnic minority and immigrant groups because their minority and immigrant status make their ethnicity more salient in the eyes of American society. A large body of research has documented the significance of ethnic identity for critical aspects of development among ethnic minority and immigrant adolescents, such as self-esteem, academic motivation, and behavioral adjustment (Phinney, 1990). Much of this work has focused on how adolescents explore or value their ethnic group membership, however, and much less is known about how teenagers come to adopt the specific ethnic labels that they use to describe themselves. Yet, the limited work on ethnic labeling has suggested that it can be consequential for adolescent development. For example, both Waters (1999) and Matute-Bianchi (1991) noted how ethnic labeling can channel adolescents from immigrant families into different peer groups, with those who identify as "Mexican" or "Jamaican" having very different social worlds than those who identify as "Chicano" or "African American." In addition, some studies have noted how these labels

also can be associated with achievement orientations and school success, with immigrant adolescents who identify with national origin labels such as "Mexican" evidencing higher levels of school success (Matute-Bianchi, 1991; Rumbaut, 1994).

Although recent research has demonstrated how adolescents can employ multiple ethnic labels to describe themselves in different contexts and settings (Harris & Sim, 2002; Moje & Martinez, 2007), an important question for adolescents from immigrant families is the extent to which they will identify with ethnic labels and categories that are distinctive to the United States and about which they may be less familiar. For example, "Latino" and "Hispanic" are pan-ethnic labels that are commonly used to refer to individuals of Latin American origin in the United States but that are absent in Latin American societies (Portes & Rumbaut, 2001). Similarly, although the terms "Asian" and "White" may not be entirely new to immigrants, their social significance is particularly American because they place adolescents within the major ethnic and racial categories used by the government and most social institutions (i.e., Black, White, Asian, Hispanic, and Native American). Another convention unique to the United States is to use the term "American" by itself or to pair national or pan-ethnic labels with the term "American" to create hyphenated labels such as "Mexican-American" and "Asian-American."

A few cross-sectional studies have indicated that adolescents from immigrant families, particularly adolescents who were born outside of the United States themselves, are somewhat resistant to adopt pan-ethnic and American ethnic labels. A survey of eighth- and ninth-grade students in Florida and Southern California reported a greater tendency to choose national origin labels such as "Mexican" and "Chinese" among the first-generation (i.e., foreign born) adolescents as compared to their second-generation (i.e., American born) peers, who were more likely to use pan-ethnic and American or hyphenated-American labels (Rumbaut, 1994). Ethnographic studies have suggested that some foreign-born adolescents, such as Black immigrants from the West Indies and immigrants from Mexico, seek to retain their national origin labels as a way to avoid the negative stereotypes associated with labels such as Black, Hispanic, or Latino (Matute-Bianchi, 1991; Waters, 1999). The pattern of first-generation adolescents preferring national origin labels and second-generation adolescents choosing pan-ethnic, American, and hyphenated-American labels has been observed in other samples (Buriel & Cardoza, 1993; Doan & Stephan, 2006), including ninth-grade students who participated in the first wave of the longitudinal study that is reported in the present article (Fuligni, Witkow, & Garcia, 2005).

Generational differences such as these are often mistakenly interpreted as meaning that spending more time in the United States will produce changes within immigrants themselves. But generational differences may not translate into changes within individuals across time and development due to the numerous confounding factors associated with generational status such as birthplace and the unique historical context within which each generation entered the country (Fuligni, 2001). It is important to determine whether ethnic labels become more Americanized within children from immigrant families across time and development to determine whether indeed more time in the United States leads to an assimilation of the society's dominant ethnic categories. As a key time of ethnic identity formation, the adolescent years are an important developmental period to study this process.

Longitudinal examinations of changes in ethnic labeling are rare and there are competing predictions about what might be observed. On the one hand, the adolescent period could be a period of significant change in ethnic labeling among those from immigrant families as they become more aware of the existence and the social significance of the ethnic categories used in American society (Doan & Stephan, 2006). The continual need in secondary school to complete official forms that require identification with a pan-ethnic group, such as Asian or Hispanic, a general desire to belong to and fit in with normative groups and social categories, and an increasing awareness of the ethnic landscape of American society could lead those from immigrant families to adopt pan-ethnic, American, or hyphenated-American ethnic labels as they progress through high school. Like most adolescents in the United States, children from immigrant families engage in the normative process of emotionally distancing themselves somewhat from their parents during adolescence (Fuligni, 1998), and this process could weaken adolescents' connection to their families' national origin and result in a movement toward other ethnic labels.

On the other hand, there may be stability in the ethnic labels chosen by adolescents from immigrant families over the high school years. Some observers have suggested that birthplace is a primary criterion by which individuals may determine their ethnic categories (Rumbaut, 1994). First-generation, foreign-born adolescents may therefore retain the national origin labels that they have been shown to prefer in previous cross-sectional studies because they believe that they will always be primarily "Mexican" or "Chinese" because of their birth in Mexico or China. Similarly, second-generation adolescents may feel unable to adopt such a national origin label because they were not born in those countries. Instead, those of the second generation may identify with labels such as Latino or Asian American throughout the adolescent years because they were born in the United States. Another possibility is that adolescents from immigrant families move toward the incorporation of national original labels even more, as their process of identity development leads them to explore their family's national and cultural origins more closely.

The Current Study

We sought to test these competing hypotheses in a longitudinal study of adolescents from Asian and Latin American immigrant families who were followed yearly during the 4 years of high school. First, we examined whether there was a normative change toward the inclusion of pan-ethnic and American (either hyphenated or alone) terms in ethnic labels as adolescents progressed through the high school years. Second, we assessed whether changes in the use of pan-ethnic and American terms varied according to the adolescents' ethnic background, generation, and gender. It is possible that adolescents from Asian immigrant families would be more likely to move in the direction of the adoption of pan-ethnic or American terms. Because of the greater economic integration of their parents and their own academic success at school, adolescents from Asian immigrant families may identify with American society more quickly than those from Latin American immigrant families (Portes & Zhou, 1993). In addition, individual Asian immigrant groups are relatively smaller in size than those from Latin America, which may lead toward greater aggregation across specific ethnic groups into a larger pan-ethnic identification. Indeed, in perhaps the only longitudinal examination of changes in ethnic labeling, Portes and Rumbaut (2000) reported that adolescents from Chinese immigrant families were more likely to move toward the adoption of a pan-ethnic label between middle school and the end of high school, whereas those from Mexican immigrant families moved away from pan-ethnic labels and toward the national origin label of "Mexican."

In terms of generational status, it is possible that there would be greater change among the foreign-born adolescents, particularly among those who come to the United States at older ages, because they start out with the endorsement of the national origin label, thereby giving them more room to move toward the inclusion of pan-ethnic and American terms as they spend more time in the United States. Second-generation adolescents, by virtue of being born in the United States, may feel that they have fewer ethnic options available to them and must conform to the ethnic categories that are dominant in American society. Finally, it is difficult to predict whether there would be gender differences in the changes in adolescents' choice of ethnic labels. Our earlier analyses of ninth-grade students who participated in the longitudinal study reported in the present article revealed no gender differences in adolescents' choice of their most descriptive ethnic labels, and gender differences were inconsistent in the Portes and Rumbaut (2001) study discussed earlier. Nevertheless, we explored potential gender differences given some previous evidence suggesting that girls in ethnic minority families were more likely to be socialized by their parents in their ethnic and cultural background (Bowman & Howard, 1985), which could lead to a lower likelihood of girls moving toward the inclusion of pan-ethnic and American terms in their ethnic labels.

In addition to examining variations in changes *between* adolescents, we analyzed changes *within* adolescents over time as a function of simultaneous changes in their family cohesion, ethnic exploration and affirmation, and proficiency in their families' heritage languages (e.g., Chinese, Spanish). Such analyses allowed us to get closer to the processes by which changes in ethnic labeling take place within adolescents by looking at how these changes are associated with changes in other significant aspects of their social and psychological development. We selected these factors because research on adolescents from immigrant families suggests that ethnic labeling may be part of a larger acculturation process that involves changes in family relationships, ethnic exploration and attachment, and language use (Phinney, 2003; Portes & Rumbaut, 2001; Tseng & Fuligni, 2000). These factors often are associated with one another on an individual differences basis, suggesting that they are part of a general process by which adolescents from immigrant families negotiate the potential differences between their cultural background and American society. As such, we believed that they might be candidates for predictors of changes in ethnic labeling *within* individual adolescents over the high school years.

In terms of family cohesion, adolescence is a period of fluctuation in parent–child relationships, and these relationships are thought to be critical factors in the retention of traditional cultural orientations in immigrant families (Gonzales, Deardorff, Formoso, Barr, & Barrera, 2006). Several observers have suggested that acculturation stress may occur between immigrant parents and their children because of the different rates at which they adapt to American society (Zhou, 1997). Therefore, it is possible that as adolescents become more emotionally distant from their parents over the high school years, their ties to their families' national and cultural origins may weaken. As a result, the adolescents may move away from ethnic labels that incorporate their national origin and toward labels that include pan-ethnic or American terms.

The strength of adolescents' ethnic identity refers to the extent to which adolescents identify with and feel attached to their ethnic group (Ashmore, Deaux, & McLaughlin-Volpe, 2004; Phinney, 1990). Two predictions could be made about the links between the strength of adolescents' ethnic identity and their choice of ethnic labels. On the one hand, stronger ethnic identity could be associated with a greater adoption of pan-ethnic and American ethnic terms. This is because a stronger ethnic identity would reflect a greater exploration of ethnic identity in the context of an American society that uses these terms to demarcate the dominant ethnic categories. In addition, stronger ethnic identity could result in a perception of common fate among members of different Asian or Latin American ethnicities, resulting in greater pan-ethnic identification (Lien, Conway, & Wong, 2003).

On the other hand, higher levels of ethnic identity could be associated with the retention of national labels because the identity exploration of adolescents from immigrant families would require them to consider their national heritage. In addition, it could simply be harder to maintain a national label in American society, thereby requiring the identity work that would be reflected in higher levels of ethnic identity. In support of the latter hypothesis, earlier analyses of ninth-grade students who participated in the first wave of the longitudinal study that is reported in the present article suggested that ethnic identity was stronger among adolescents who primarily chose a national origin label (Fuligni et al., 2005).

Our expectation for the links between changes in adolescents' proficiency in their heritage language and their ethnic labels was straightforward. Given the meaning of language use and proficiency for ethnic and cultural identity that has been observed previously among immigrant families and adolescents (e.g., Phinney, Romero, Nava, & Huang, 2001), lower levels of adolescents' heritage language proficiency across the high school years were expected to be associated with a less use of the national origin label and more use of pan-ethnic and American terms.

Method

Sample

Beginning in 9th grade and continuing yearly through 12th grade, students from three public high schools in the Los Angeles area were recruited for participation in a longitudinal study. The first school was populated predominantly by students who came from families with Latin American and Asian backgrounds with lower-middle to middle-class educational and occupational statuses. This school tended to be in the lower middle to middle range of the achievement distribution of schools within the state of California (California Department of Education, 2006). The second school possessed average levels of achievement and consisted mainly of students from Latin American and European backgrounds whose families had lower-middle to middle-class backgrounds. Finally, the third school mainly consisted of students from families with Asian and European backgrounds who were middle- to upper-middle-class in terms of parental education and occupation. The third school tended to have above average achievement levels. No single ethnicity dominated any of these schools; rather, the two largest ethnic groups each comprised 30%–50% of the total population in each school (California Department of Education, 2006).

In two of the schools, the entire ninth grade was invited to participate during the 1st year of the study. At these schools, the same process continued in subsequent years, with all students in the correct grade being invited to participate. In the third school, approximately half the ninth graders were invited to participate because the large size of the school did not make it feasible to recruit all the students. In this school, only students who had participated in ninth grade were followed in subsequent years. At all three schools, students who had participated in earlier years but were no longer enrolled in the school were contacted and invited to participate by mail in subsequent years.

The sample used in the present analyses was the 384 participants from Asian and Latin American immigrant families who had completed self-report questionnaires for at least 2 of the 4 years of the study, where an immigrant family was defined as one in which at least one parent was foreign born. The mean ages of the sample ranged from 14.87 years (*SD* =

0.39) at the 9th grade to 17.82 years ($SD = 0.38$) at the 12th grade. The sample was evenly split by sex (187 male and 197 female). The majority of the 228 participants from Asian immigrant families were from Chinese backgrounds (76.8%), and the majority of the 156 participants from Latin American immigrant families had Mexican backgrounds (86.5%). Of the Asian participants, 78 were of the first generation (i.e., the students were foreign-born themselves) and 150 were of the second generation (i.e., the students were born in the United States). Of the participants from Latin American families, 35 were of the first generation and 121 were of the second generation. The average ages at which first-generation adolescents came to the United States were 7.88 and 4.07 years (SDs = 4.15 and 3.44) for those from Asian and Latin American backgrounds, respectively.

Adolescents from the two immigrant groups differed in terms of parental education such that the Asian immigrant parents were more likely to have graduated from high school and attended some college than the parents from Latin America, $F(1, 371) = 28.58, p < .001$. There were no differences in parental education according to the adolescents' generational status, $F(1, 371) = .89$, *ns*, and the relationship between ethnicity and education did not vary according to generational status, $F(1, 371) = .07$, *ns*.

Measures

Participants completed the following measures in self-report questionnaires during each year of the study. Questionnaires were available to students in English, Chinese, and Spanish and fewer than 8 participants chose to complete the questionnaires in a language other than English during any single year.

Ethnic labeling. Adolescents were presented with an alphabetical list of ethnic labels that is shown in Appendix. The list was developed based on discussions with ethnically diverse adolescents, discussions with Mexican and Chinese undergraduate research staff members who attended high school in the Los Angeles area, and prior research on the type of labels used by adolescents from these different groups (e.g., Matute-Bianchi, 1991; Rumbaut, 1994). Adolescents were asked to indicate all the labels that they felt applied to them and to add any others that applied to them but that were not on the list (e.g., mixed-race labels, other ethnic labels). Additionally, students were asked to indicate the ethnic label that they believed best described them. Adolescents were allowed to report more than one label for the last question about the best descriptive label if they felt that it was most accurate for their own ethnic identity, but this was done by less than 3% of the sample during any given year.

Each year, labels were coded as to whether a pan-ethnic term (e.g., Asian, Latino) or an American term, either by itself or hyphenated (e.g., American, Mexican-American), was included in the label. In addition, labels were coded as to whether they referred to solely national origin (e.g., Mexican, Chinese). The vast majority of adolescents included pan-ethnic/American labels (98.7%) and national origin labels (89.6%) in their total list of chosen labels during at least 1 year of the study, providing support to the idea that both types of labels are used by adolescents during the high school years. Our analyses focused on the labels with which adolescents identified most strongly, which were those that adolescents reported described them best. For these analyses, the most descriptive label was coded as to whether it included a pan-ethnic or an American term, either by itself or hyphenated (0 = *no*, 1 = *yes*). Similar findings to those reported in the Results section were found when choice of pan-ethnic and American labels were each analyzed separately. Of the 3% of adolescents who reported multiple most descriptive labels, all but two adolescents reported labels that could both be classified into the same categories described earlier (e.g., pan-ethnic and national origin). The two participants who listed multiple most descriptive labels that fell into different categories were not included in the present analyses. The specific labels chosen by adolescents as most descriptive each year are presented in Table 1.

Closeness to parents. Adolescents completed a subset of the Family Adaptation and Cohesion Evaluation Scales II inventory separately for each parent (Olson, Sprenkle, & Russell, 1979). Questions were the same for mothers and fathers and participants responded to each on a 5-point scale (1 = *almost never*, 5 = *almost always*). The measure for each parent included 10 items such as "My mother [father] and I do things together," "My mother [father] and I are supportive of each other during difficult times," and "My mother [father] and I feel very close to each other." An average was computed for each participant across both parents. Internal consistencies were similarly high for both ethnic groups across the 4 years of the study (αs = .87 – .92). Scores were recoded on a 0–4 scale for the analyses presented in this article.

Strength of ethnic identity. Adolescents completed two subscales of the Multigroup Ethnic Identity Measure (Phinney, 1992) in reference to the most descriptive ethnic label that they chose each year.

Table 1
Frequencies of Most Descriptive Labels

Uruguayan	0.9							
Vietnamese					3.4	5.4	3.5	3.5
Vietnamese American					6.8	5.4	7.0	7.9

Note. Figures refer to the percentage of adolescents within each ethnic group at each grade level who chose each label as their most descriptive label. Any label that included the term "American," by itself or in combination with another term, was coded as including an American term except for "Central American." Any label that included "Asian," "Chicano/a," "Latino," and "Hispanic," either alone or in combination with another term, was coded as including a pan-ethnic term.

The Affirmation and Belonging subscale consists of seven items and assesses ethnic pride, feeling good and happy about one's ethnicity, and feelings of belonging and attachment to one's ethnic group. Sample items include "I am happy that I am a member of the group I belong to," "I have a lot of pride in my ethnic group" and "I feel good about my cultural or ethnic background." The Ethnic Identity Search subscale consists of five items and measures individuals' exploration of and commitment to their ethnic group. Sample items include "I have spent time trying to find out more about my ethnic group, such as its history, traditions, and customs," "I am active in organizations or social groups that include mostly members of my own ethnic group," and "In order to learn more about my ethnic background, I have often talked to other people about my ethnic group." Participants responded to each item on a 5-point scale (1 = *strongly disagree*, 5 = *strongly agree*). Internal consistencies were similarly high for both ethnic groups across the 4 years of the study for both measures (affirmation: αs = .89 – .91, search: αs = .68 – .78). Scores were recoded on a 0 – 4 scale for the analyses presented in this article.

Heritage Language Proficiency

Using a standard approach to measuring language proficiency in large-scale questionnaire studies that prohibit the direct testing of language proficiency (e.g., Phinney et al., 2001; Portes & Rumbaut, 2001), adolescents were asked to report all the languages that were spoken in their home. For any non-English language spoken in the home (e.g., Chinese, Spanish), participants were asked to rate how well they speak, understand, read, and write that language. Participants responded to each item on a 5-point scale (1 = *not very well*, 5 = *very well*), and responses to these multiple items of proficiency were averaged. Participants received a 0 on this scale if they indicated that no non-English languages are spoken in their home, resulting in a scale that ranged from 0 to 5. Internal consistencies were similarly high for both ethnic groups across the 4 years of the study (αs = .86 – .89).

Results

Participation Analyses

Initial analyses were conducted to examine differences between adolescents according to the degree of their participation in the study. Although this sample could include those who participated only 2 years, most participated all 4 years of the study (*M* = 3.52 years, *SD* = 0.67). Because participants entered the study at different years, a variable was created to indicate the percentage of possible years each participant took part in the study. For example, a participant who began the study in 9th grade had four possible years, whereas a participant who began the study in

10th grade only had three possible years. On average, participants took part in the study in 94% ($SD = 0.14$) of their possible years. There were no differences in the degree of participation as a function of gender, ethnicity, or generation. To determine if there were differences in any of the time varying variables (i.e., ethnic labeling, closeness to parents, strength of ethnic identity, and heritage language proficiency) as a function of participation, hierarchical linear models (HLM; Bryk & Raudenbush, 1992) were estimated using the following equations:

$$\text{Ethnic labeling, etc.}_{ij} = b_{0j} + e_{ij} \qquad (1)$$

$$b_{0j} = c_{00} + c_{01}(\text{participation}) + u_{0j} \qquad (2)$$

where Equation 1 represents adolescents' scores on the time varying variables (i.e., ethnic labeling, closeness to parents, etc.) across the years of their participation in the study and Equation 2 represents the prediction of the adolescents' average scores across their years of participation as a function of their degree of participation (i.e., the percentage of possible years that they took part in the study). There were no differences in any of the variables in the study based on degree of participation except for heritage language proficiency, where adolescents who participated in more years of the study had lower average levels of heritage language proficiency ($b = -1.40$, $p < .01$).

For this analysis and all subsequent analyses described subsequently, additional hierarchical generalized linear models (HGLM) were tested because the outcome variable had only two possible values. Except in the one minor case noted subsequently, the substantive results remained unchanged. For ease of presentation and interpretation, results from the HLM are presented throughout.

Normative Changes in Ethnic Labeling

The first goal of this study was to examine change over time in adolescents' inclusion of a pan-ethnic or an American term in their most descriptive ethnic label. The statistical model that was estimated was as follows:

$$\text{Panethnic or American term}_{ij} = b_{0j} + b_{1j}(\text{year}) + e_{ij} \qquad (3)$$

$$b_{0j} = c_{00} + c_{01}(\text{gender}) + c_{02}(\text{ethnicity}) + c_{03}(\text{generation}) + u_{0j} \qquad (4)$$

$$b_{1j} = c_{10} + c_{11}(\text{gender}) + c_{12}(\text{ethnicity}) + c_{13}(\text{generation}) + u_{1j} \qquad (5)$$

As shown in Equation 3, adolescents' inclusion of a pan-ethnic or an American term (0 = *no*, 1 = *yes*) on a particular year (i) for a particular individual (j) was modeled as a function of the average amount of inclusion of the term by the individual (b_{0j}) and the year of the study (b_{1j}). Year was coded such that *Year 1* = 0, *Year 2* = 1, *Year 3* = 2, and *Year 4* = 3. Equations 4 and 5 show how both the average amount of inclusion and the effect of the year of the study were modeled as a function of the adolescents' gender, ethnicity, and generational status. The Level 2 variables were effects coded such that gender was coded as *males* = −1 and *females* = 1, ethnicity was coded as *Latino* = −1 and *Chinese* = 1, and generation was coded as *first generation* = −1 and *second generation* = 1.

Results indicated no normative developmental changes in adolescents' inclusion of a pan-ethnic or an American term in their most descriptive ethnic labels. On average, second-generation adolescents were more likely to choose a pan-ethnic or an American term (Table 2). But as shown in Table 2 and Figure 1, there were no significant changes in ethnic labeling over time ($b = -.02$, *ns*). Further, there was no significant variation in the effect of time on labeling (*SD* of estimate = 0.05, *ns*) and the amount of change did not significantly vary across adolescents' gender, ethnicity, and generation.

An additional analysis was conducted with first-generation participants to test whether amount of change varied according to age of immigration. For

Ethnicity	.01 (0.01)
Generation	−.01 (0.01)

Note. Gender was coded as *boys* = −1, *girls* = 1; ethnicity was coded as *Latino* = −1, *Asian* = 1; and generation was coded as *first generation* = −1, *second generation* = 1. All predictors were uncentered.
$^{***}p < .001$.

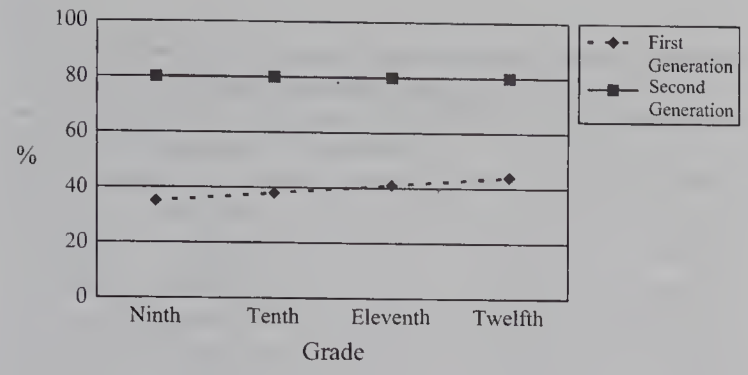

Figure 1. Change over time in likelihood of including a pan-ethnic or an American term in adolescents'ethnic label according to generation.

this analysis, generation in Equations 4 and 5 was replaced with age of immigration, which was centered at the mean of the sample. With older ages of immigration, participants were less likely to choose a pan-ethnic or an American label ($b = -.03, p < .05$). However, fluctuations in ethnic labeling over time did not significantly vary according to age of immigration.

Within-Person Changes in Ethnic Labeling

Amount of within-person change. Although there was not a normative trend regarding the inclusion of a pan-ethnic or an American term in adolescents' ethnic labels over time, there was a substantial amount of change in any direction (i.e., toward or away from inclusion of a pan-ethnic or an American term) within individuals during the 4 years of high school. Overall, 47.8% of the sample changed whether or not they included a pan-ethnic or an American term in their most descriptive label over at least one grade interval during the 4 years of high school. As shown in Figure 2, between 18.2% and 22.3% of the sample changed whether they included a pan-ethnic or an American term in their label at each grade interval. Likelihood of changing whether or not a pan-ethnic or an American term was included in the label varied according to generation across the final grade interval, between 11th and 12th grades, $\chi^2(1, N = 288) = 5.10, p < .05$, such that first-generation adolescents were more likely to change. There were no ethnic differences and no other generation differences in the likelihood of changing whether a pan-ethnic or an American term was included in adolescents' most descriptive label.

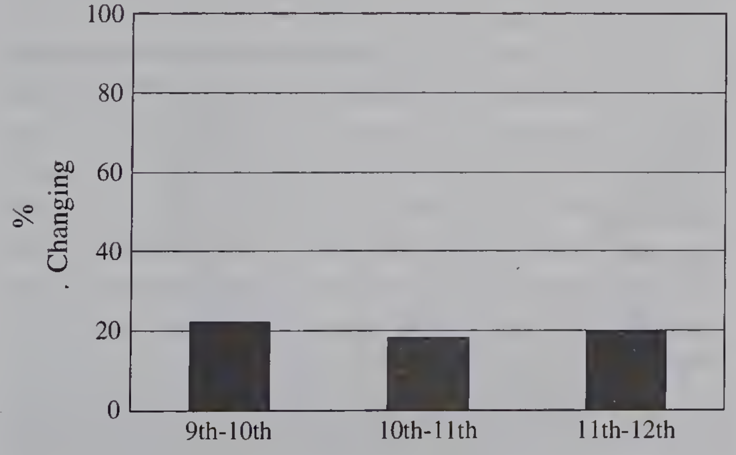

Figure 2. Percentage of adolescents changing as to whether a pan-ethnic or an American term was included in their ethnic label.

Given the degree of changes in ethnic labeling within adolescents across time, an additional set of HLM was estimated to determine whether changes in adolescents' inclusion of a pan-ethnic or an American term from year to year were associated with concurrent changes in their closeness with parents, strength of ethnic identity, and heritage language proficiency. Separate models were estimated for each of the predictor variables (closeness with parents, strength of identity, and heritage language proficiency). Given that there was a maximum of four time points per person and that some participants had only two or three time points, we did not have enough power and degrees of freedom to estimate all the predictors simultaneously. The general form of the model used for these analyses was as follows:

$$\text{Pan-ethnic or American term}_{ij} = b_{0j} + b_{1j}(\text{predictor}) + e_{ij} \tag{6}$$

$$b_{0j} = c_{00} + c_{01}(\text{gender}) + c_{02}(\text{ethnicity}) + c_{03}(\text{generation}) + u_{0j} \tag{7}$$

$$b_{1j} = c_{10} + c_{11}(\text{gender}) + c_{12}(\text{ethnicity}) + c_{13}(\text{generation}) + u_{1j} \tag{8}$$

Equation 6 shows how adolescents' selection of a pan-ethnic or an American term (0 = *no*, 1 = *yes*) on a particular year (i) for a particular individual (j) was modeled as a function of the average amount of inclusion of the term by the individual (b_{0j}) and the specific predictor variable (b_{1j}; i.e., closeness with parents, strength of ethnic identity, or heritage language proficiency). Closeness with parents and strength of identity were coded from 0 to 4 and heritage language proficiency was coded from 0 to 5. Equations 7 and 8 show how the average amount of inclusion of the term and the effect of the predictor variable were modeled as a function of gender, ethnicity, and generational status, which were coded in the same manner as before.

As before, an additional analysis was conducted with first-generation participants, in which generation in Equations 7 and 8 was replaced with age of immigration. In no case, did the relationship between the predictor and the selection of a pan-ethnic or an American label vary according to age of immigration.

Closeness with parents. As shown in Table 3, there was no association between changes in closeness with parents and changes in the inclusion of an American or pan-ethnic term in adolescents' most descriptive ethnic label ($b = .00$, *ns*).

Strength of ethnic identity. Separate analyses were performed using ethnic search and ethnic affirmation. As shown in Tables 4 and 5, lower levels of search and affirmation were each associated with a greater likelihood of adolescents including a pan-ethnic or an American term in their most descriptive ethnic label each year (search: $b = -.04$, $p < .01$; affirmation: $b = -.08$, $p < .001$). However, the relationship between affirmation and label choice was moderated by generation such that the association was significant for first-generation participants ($b = -.13$, $p < .001$) but not for second-generation participants ($b = -.03$, *ns*). The analysis examining the relationship between affirmation and likelihood of including a pan-ethnic or an American label in one's most descriptive label was the one instance in which the results varied between HLM and HGLM. In the HGLM, there was a significant relationship between affirmation and label choice that was not moderated by generation.

Heritage Language Proficiency

As shown in Table 6, lower levels of heritage language proficiency were associated with a greater likelihood of including a pan-ethnic or an American label in one's most descriptive label ($b = -.05$, $p < .01$) each year. However, this relationship was moderated by generation such that the association was significant for first-generation participants ($b = -.08$, $p < .01$) but not for second-generation participants ($b = -.01$, *ns*).

Parental Education

A final set of analyses was conducted using parental education as an additional predictor in Equations 4, 5, 7, and 8 to determine whether it was associated with any of the patterns reported earlier and whether it might explain any observed ethnic or generational differences. Parental education was a significant predictor in only one of the analyses: Among adolescents with more highly educated parents, the negative association between the heritage language proficiency

and the inclusion of an American term was reduced ($b = .02, p < .05$). In no case, however, did the inclusion of parental education change any of the results regarding ethnicity or generation reported earlier.

Discussion

Adolescents from immigrant families showed no normative trend toward the inclusion of pan-ethnic and American terms in their most important ethnic labels across the high school years. Generational changes remained stable during high school, with second-generation students being more likely to use pan-ethnic and American terms than first-generation students, testifying to the continued importance of birthplace in adolescents' choice of the ethnic labels with which they identify most closely (Rumbaut, 1994). Even after spending more years in American society, many foreign-born adolescents likely feel unwilling or unable to identify primarily with the ethnic labels common to the United States because they were born in other countries, such as Mexico or China. Second-generation adolescents, in turn, may feel unable to consider themselves primarily "Mexican" or "Chinese" because they were not born in those countries. Although first-generation adolescents who arrived in the United States at earlier ages were more likely to use pan-ethnic and American terms on average, the lack of change over time according to age of immigration suggests that it is the age at which the adolescents enter the United States that makes a difference rather than the number of years they have spent in the country. Ethnic differences also remained stable across time. The trend for adolescents from Asian immigrant families to more likely use an American term in their most important ethnic label may be due to a greater identification with American society resulting from their higher level of academic success and their families' relatively easier economic integration as compared to those from Latin American backgrounds (Portes & Zhou, 1993).

The lack of normative change toward the inclusion of pan-ethnic and American terms in adolescents' most important label demonstrates how differences across different generations do not necessarily mean that more time in the United States will produce changes within immigrants themselves (Fuligni, 2001). At least during the high school years, adolescents from immigrant families as a whole do not show changes that would imply acculturation or assimilation to the dominant ethnic categories and labels used in American society. It is possible that the stability may be a function of the relative constancy of the social environments of the students during high school. The contexts of the adolescents' lives show little change between the 9th and 12th grades as they attend the same schools with generally the same peers and teachers. Instead, normative changes in ethnic labeling may be more likely to occur at periods of social transition, such as the move out of high school and into young adulthood. As young adults gain new experiences through work or education, they may become more deeply aware of their ethnic background (Phinney, 2003). Practically speaking, young adults often use their newly found independence and their college and work experiences to immerse themselves in diverse perspectives, student or professional organizations, and coursework to explore and learn more about their identity (Tatum, 1997). It would be important in future work to follow adolescents from immigrant families during such a significant period of developmental transition, although it is unlikely that generational differences would ever disappear completely as studies of adults have found consistent generational differences in ethnic labeling (Lien et al., 2003; Masuoka, 2006).

Although there was great stability in the overall numbers of adolescents who chose different ethnic labels during high school, there were changes within adolescents themselves from year to year. Therefore, rather than a period of great stability, the high school years are a time of fluctuation in the ethnic labels with which adolescents most closely identify. The fluctuation is not in any one direction. Rather, adolescents from immigrant families appear to be trying on different ethnic labels each year, and similar numbers of students move toward and away from the use of a pan-ethnic or an American term. Such fluctuation would be consistent with the portrayal of the adolescent years as a key period in the developmental of ethnic identity, which usually involves a process of search and exploration of one's cultural background and place in American society (Phinney, 1990).

Rather than being random fluctuation, however, the changes in most important ethnic labels within adolescents themselves were significantly associated with changes in other significant aspects of the adolescents' psychological and social development thought to be central to the larger acculturation process of adolescents from immigrant families (Phinney, 2003; Portes & Rumbaut, 2002, Tseng & Fuligni, 2001). Changes in the strength of adolescents' ethnic identity predicted changes in their ethnic labeling, with lower levels of ethnic search and affirmation being associated with the greater probability of including pan-ethnic and American terms. The process of ethnic identity development, although it takes place in a social context in which pan-ethnic and American terms are dominant, likely requires adolescents from immigrant families to consider their national heritage. Retaining a national origin label such as "Mexican" or "Chinese" may require more identity work and effort, which would be reflected in higher levels of ethnic search and affirmation. The inclusion of pan-ethnic and American terms, in contrast, could partially be a result of simply accepting the ethnic categories that American society places adolescents into through school forms and other official documents that allow for identification with only pan-ethnic or hyphenated-American labels. Accepting these labels, therefore, may require lower levels of ethnic search and affirmation.

Change in adolescents' heritage language proficiency was associated with changes in their most important ethnic labels such that lower levels of proficiency were associated with a greater probability of including pan-ethnic and American terms. Language use and proficiency have been shown to be linked to the strength of adolescents' ethnic identity in previous research (Phinney et al., 2001). The ability to speak their families' heritage language, such as Spanish or Chinese, likely enables adolescents to explore their families' cultural and national heritage more deeply through communication with family members and consumption of non-English information sources and media. Adolescents from immigrant families also may feel that they cannot consider themselves primarily "Mexican" or "Chinese" if they cannot speak the language very well. Continued research should more thoroughly explore the meaning of language use and ability for ethnic labeling and identity through the use of qualitative methods such as in-depth personal interviews and focus groups.

Interestingly, the link between changes in heritage language ability and changes in the inclusion of a pan-ethnic or an American label varied such that it was stronger for first-generation adolescents as compared to second-generation adolescents. This may be because of the high level of heritage language ability of the first-generation adolescents, who were born outside of the United States. As a result, heritage language ability may have more meaning for these teenagers, and it may be seen as a greater indicator of identification with and connectedness to the family's country and culture of origin. For second-generation adolescents, heritage language ability appears to be less of a meaningful indicator for ethnic and cultural identity.

In contrast to the strength of ethnic identity and heritage language proficiency, changes in closeness with parents were not predictive of changes to ethnic labeling. It may be that ethnic labeling is more dependent upon social and psychological factors most closely tied to ethnicity and culture than more generic aspects family relationships. In addition, it is important to note that the associations of strength of ethnic identity and heritage language proficiency with ethnic labeling were observed *within* adolescents themselves, thereby ruling out potential confounding factors associated with traditional correlations observed between adolescents. Rather, the associations observed in this study suggest that these social processes are closely linked to one another among adolescents from immigrant families.

The results of this study highlight how adolescents from immigrant families appear to be exploring and experimenting with different ethnic labels across the high school years, and it is important in continuing work to examine how these explorations vary across different social contexts and settings. The ethnic context of adolescents' neighborhoods and schools should make a difference in the labels that they use to describe themselves. Adolescents who participated in this study all lived in contexts in which there are substantial numbers of adolescents from similar immigrant and ethnic backgrounds, thereby potentially leading toward lower rates of inclusion of pan-ethnic and American terms in their ethnic labels. The present study was unable to determine whether variation in the ethnic and immigrant concentration across schools and neighborhoods would make a difference in adolescents' ethnic labels, but it is possible that higher levels of pan-ethnic and American labeling would be observed among immigrants in contexts with few other coethnics. Given the increased dispersal of immigrants to nontraditional receiving locations in the United States, this would be an important topic for future research.

Other studies have suggested that the use of different ethnic labels may vary contemporaneously across different proximal social settings, such as school, home, and peer groups (Harris & Sim, 2002; Moje & Martinez, 2007). It would be useful in future research to combine the approach taken in this study with methods that assess multiple settings to obtain a fuller understanding of the explorations and fluctuations that take place in ethnic labeling during the adolescent years.

Additional studies also can examine the role of other psychological and social factors in adolescents' choice of ethnic labels. Experience with discrimination has been suggested to play a role in the ethnic identification of adolescents from immigrant families, yet the direction of the effect is unclear. Waters (1999) reported that adolescents who did not identify with their parents' West Indian cultural background and instead identified with labels such as Black and African American tended to report more frequent experiences with discrimination. In contrast, Portes and Rumbaut (2001) found that adolescents from immigrant families who identified with their parents' national origin reported the highest levels of discrimination. A clearer understanding of the role of discrimination could be obtained by better analyzing the precise social meanings and social positioning of individual ethnic labels (e.g., Mexican vs. Latino vs. Chinese vs. Asian), as well as the ways in which adolescents from immigrant families themselves make sense of those social meanings. In addition to examining discrimination, closer analyses of adolescents' friendships, attitudes toward American society, and involvement in cultural activities and organizations would be important to examine.

In summary, although ethnic labeling showed no normative trend of acculturation or assimilation, the high school years represent a period of fluctuation in the labels that adolescents from immigrant families identify with most closely. These fluctuations appear to be tied to fluctuations in other significant aspects of their psychological and social development, and future research should expand the developmental periods, social settings, and potential predictors being assessed to better understand a process that is an important component of the acculturation and development of adolescents from immigrant families.

A Developmental Perspective on Full- Versus Part-Day Kindergarten and Children's Academic Trajectories Through Fifth Grade

Elizabeth Votruba-Drzal
University of Pittsburgh

Christine P. Li-Grining
Loyola University Chicago

Carolina Maldonado-Carreño
University of Pittsburgh

Children's kindergarten experiences are increasingly taking place in full- versus part-day programs, yet important questions remain about whether there are significant and meaningful benefits to full-day kindergarten. Using the Early Childhood Longitudinal Study's Kindergarten Cohort (N = 13,776), this study takes a developmental approach to examining associations between kindergarten program type and academic trajectories from kindergarten (ages 4–6 years) through 5th grade (ages 9–12 years). Full-day kindergarten was associated with greater growth of reading and math skills from fall until spring of kindergarten. Initial academic benefits diminished soon after kindergarten. The fade-out of the full-day advantage is in part explained by differences in the children who attend part- and full-day kindergarten as well as school characteristics.

Over the past 35 years, kindergarten programs in the United States have been transformed. When states and localities began implementing publicly funded kindergarten in the 1960s and 1970s, they consisted mostly of part-day programs and focused on easing young children's transitions to school by providing opportunities to socialize and play in group settings. Fewer than 15% of all 5-year-olds attended full-day programs in the 1970s (Elicker & Mathur, 1997). In recent years, the number of children attending full-day kindergarten programs has nearly doubled. At the beginning of the 1980s, just over 25% of U.S. children in kindergarten attended full-day programs (Burriss, 2000). By the end of the 1990s, this number grew to more than 55% (Walston & West, 2004).

As the number of children in full-day kindergarten programs has grown, so too has research comparing the effects of full- and part-day kindergarten on children's academic achievement (for a review, see Lee, Burkam, Ready, Honigman, & Meisels, 2006). Existing research on the benefits of full-day kindergarten has largely been conducted outside the developmental literature, where studies have focused mostly on the educational aspects of full-day kindergarten (Lee et al., 2006) or the policy debates surrounding full-day kindergarten (Cannon, Jacknowitz, & Painter, 2006). Though effects on children's development are of primary interest in studies of full-day kindergarten programs, developmental models and analytic techniques have rarely been used in research comparing full- and part-day kindergarten. Grounded in bioecological theory, the goal of this study was to contribute a developmental perspective to the literature on kindergarten program type (Bronfenbrenner, 1979; Bronfenbrenner & Morris 2006). Using data from the Early Childhood Longitudinal Study's Kindergarten Cohort (ECLS–K), we examine whether kindergarten program type is linked to initial gains in children's achievement trajectories, after taking into account important characteristics of out-of-school contexts and heterogeneity in the development of academic skills. Furthermore, we consider how long into the elementary school years the advantage of full- versus part-day kindergarten lasts.

Are There Benefits to Attending Full-Day Kindergarten?

Though some investigations on the benefits of attending full-day kindergarten have not found

---

The research reported in this article was made possible by a fellowship from the Spencer Foundation. The views expressed are our own and do not necessarily reflect the views of the Spencer Foundation. We thank Emma Adam, Lindsay Chase-Lansdale, Tom Cook, Greg Duncan, Bob Pianta, Fred Morrison, and Sean Reardon for their comments on prior drafts of this manuscript. We also thank Mathilda du Toit for technical support she provided for the HLM software. Any errors that remain are ours. A special thank you is also extended to the children and families who participated in the Early Childhood Longitudinal Study's Kindergarten Cohort.

differences between children enrolled in full- versus part-day programs, more studies have documented significant benefits of full-day kindergarten for children's academic skills (for a review, see Lee et al., 2006). When compared to children attending part-day kindergarten, those attending full-day kindergarten tend to perform better on tests of reading, math, and science achievement, and have lower levels of special education placements and grade retention (Cannon et al., 2006; Clark & Kirk, 2000; Cryan, Sheehan, Wiechel, & Bandy-Hedden, 1992; Elicker & Mathur, 1997; Entwisle, Alexander, Cadigan, & Pallas 1987; Gullo, 2000; Gullo, Bersani, Clements, & Bayless, 1986; Kaplan, 2002; Karweit, 1992; Lee et al., 2006; Walston & West, 2004; Weiss & Offenberg, 2002). Overall, these advantages tend to be small to moderate.

A Developmental Approach to Studying Full-Day Kindergarten

Noticeably absent from existing research on the benefits of full-day kindergarten have been the voices of developmental scholars, which is rather surprising, given the developmental nature of this policy question. At the core of discussions about kindergarten program type is the question of whether full-day kindergarten is associated with meaningful differences in children's individual achievement trajectories during the kindergarten year and beyond, net of other important contexts that shape their development. Developmental theory and analytic techniques are poised to make an important contribution to this policy discussion (Foster & Kalil, 2005). Developmental science highlights both the multicontextual nature of environmental influences on children's lives and the heterogeneity of developmental trajectories. By incorporating these two core tenets of developmental psychology into our analysis of kindergarten program type, we hope to strengthen our understanding of the benefits of full-day kindergarten attendance to children's academic achievement.

Recognizing multiple contexts of children's development. Almost 30 years ago, Bronfenbrenner (1979) advanced the field of child development by introducing Ecological Systems Theory, which recognizes the embeddedness of children's lives in multiple contexts. In what subsequently became known as the bioecological model of human development, Bronfenbrenner argued for the study of child development in ecological context or, as he stated so clearly, "in the actual environments in which human beings lived their lives" (Bronfenbrenner & Morris, 2006, p. 794). Although children's experiences in school play a prominent role in shaping their development throughout middle childhood, other contexts including families and nonparental care settings have important influences on children's development. Yet, studies comparing full- versus part-day kindergarten have not sufficiently taken into account the influences of these out-of-school settings.

Studies have repeatedly demonstrated that families represent the most influential context in children's lives (Coleman, 1966; National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2002). An important aspect of families' lives that has received notably less attention in the literature on full-day kindergarten is the cognitive stimulation parents provide for their children. Yet, learning experiences in the context of the home environment play a central role in shaping the development of children's academic skills during the preschool and early elementary school years (Morrison, Bachman, & Connor, 2005). Global measures of cognitive stimulation in the home environment have been linked to children's vocabulary, reading, and math skills (Bradley, Corwyn, Burchinal, McAdoo, & Garcia Coll, 2001; Smith, Brooks-Gunn, & Klebanov, 1997). These measures cover a broad range of learning experiences including the frequency with which parents read to children; teach them letters, numbers, and shapes; and provide them with cognitively stimulating toys.

One salient dimension of families' lives that has been addressed in research on full-day kindergarten is the economic condition of children's households (e.g., Cannon et al., 2006). One fifth of young children in the United States live in poverty (National Center for Children in Poverty, 2006), which prior studies have consistently identified as a risk factor for children's academic and cognitive skills (Dearing, McCartney, & Taylor, 2001; Duncan & Brooks-Gunn, 1997; McLoyd, 1998; Patterson, Kupersmidt, & Vaden, 1990; Shonkoff & Phillips, 2000; Votruba-Drzal, 2006). Children from economically disadvantaged households tend to experience less consistent, supportive, and cognitively stimulating caregiving than those from middle- and upper-class families (Votruba-Drzal, 2003, 2006). Moreover, children from low-income households face a variety of risk factors that threaten their health and development. They are, for example, more likely to be raised in a single-parent household, have a teenage mother, experience family instability, and grow up in a neighborhood characterized by high levels of violence (Brooks-Gunn, Klebanov, & Liaw, 1995; Evans & English, 2002; Rutter, 1981). Particularly detrimental to children's academic competence is economic hardship that occurs during early childhood, as economic gaps in early academic achievement tend to continue and to exacerbate in middle childhood (Alexander, Entwisle, & Dauber, 1993; Duncan & Brooks-Gunn, 1997; Duncan, Brooks-Gunn, Yeung, & Smith, 1998; Entwisle, Alexander, & Olson, 1997; Votruba-Drzal, 2006).

Beyond the home environment, child-care settings have become increasingly important contexts for children's development, as women have entered the labor force in higher numbers. Several characteristics of child-care settings have been linked to the development of children's academic skills over time, including the number of hours per week children are in care (Bogenschneider & Steinberg, 1994; Broberg, Wessels, Lamb, & Hwang, 1997; Brooks-Gunn, Han, & Waldfogel, 2002; Field, 1991; Harvey, 1999; NICHD, 2000; Votruba-Drzal, Coley, & Chase-Lansdale, 2004) and the type of care that children experience, with center-based care being linked to better academic performance than home-based settings and parental care (Broberg et al., 1997; Caughy, DiPietro, & Strobino, 1994).

Despite the roles home and child-care environments play in shaping children's development, these out-of-school contexts have been left largely unexamined in studies of full- versus part-day kindergarten. This may be especially problematic in regard to studying kindergarten program type because part-day kindergarteners likely spend the majority of their time in home and child-care settings. If children's experiences outside school are related to their academic skills and their parents' selection of kindergarten, then the failure to take these important contexts into account when considering the effects of full- versus part-day kindergarten may produce misleading results.

Mapping trajectories of achievement. A central concept in developmental science is the notion that children's development is characterized by unique trajectories, with some children developing at faster rates than others across time (National Research Council and Institute of Medicine, 2000). A handful of existing studies that have followed children beyond kindergarten suggest that although there are initial benefits to full-day kindergarten, these advantages do not persist after the early years of elementary school. These studies show that the academic disadvantages of part-day kindergarten fade out sometime between first and third grade (Karweit, 1987; Ohio State Legislative Office of Education, 1997; Weiss & Offenberg, 2002). For example, in a recent study using nationally representative data and rigorous analytic techniques, Cannon et al. (2006) found that full-day kindergarten participation was related to modestly higher reading and math scores at the end of the kindergarten year when compared to part-day kindergarten enrollment. After the kindergarten year, however, part-day kindergarten children caught up to their full-day kindergarten counterparts. The disadvantage of attending part-day kindergarten was greatly diminished by first grade and completely eliminated by the spring of third grade.

Much of the literature examining associations between kindergarten program type and academic achievement has been limited to two repeated assessments and has, therefore, not been able to account for the variability in children's growth in academic achievement when comparing the achievement outcomes of part-day kindergarteners to full-day kindergarteners. Furthermore, a focus on two repeated assessments cannot adequately capture the shape of children's academic trajectories. In short, research in this area has conceived of child development as occurring uniformly and incrementally across children. Indeed, nearly all studies of kindergarten program type have relied on the analysis of two waves of achievement scores (e.g., change models or residualized change models) taken before and after exposure to full- versus part-day kindergarten to identify associations between children's full- versus part-day kindergarten attendance and academic achievement. In doing so, studies have conceptualized full- versus part-day kindergarten's effects on children's development as providing incremental gains to achievement that are accrued between the beginning and the end of the kindergarten year and have not been able to provide detailed information about when the advantages of full-day kindergarten attendance subside.

Though the analysis of change scores has benefits for reducing potential sources of bias (Allison, 1990; Willett, 1988), they are characterized by significant limitations that have been reviewed extensively in the literature (Rogosa, Brandt, & Zimowski, 1982; Singer & Willett, 2003; Willett, 1988). Among the most significant limitations are that these approaches do not recognize two central concepts in developmental science: that child development is heterogeneous and that patterns of child development are more accurately portrayed by careful estimation of trajectories of individual growth rather than by simple change scores.

Over the past 20 years, there has been a reorientation in developmental research from what Willett (1988) refers to as a focus on *change* to more nuanced models of *growth*. Advances such as hierarchical linear modeling (HLM) have paved the way for more precise estimation of children's individual-specific growth trajectories (Burchinal & Appelbaum, 1991; Burchinal, Nelson, & Poe, 2006; Raudenbush & Bryk, 2002; Singer & Willett, 2003). These approaches to measuring development, however, have not yet been applied to the question of whether full-day kindergarten has meaningful implications for children's achievement trajectories. Nevertheless, these methods are an integral part of a developmental perspective because they recognize the heterogeneous nature of development. Here, we specifically use HLM to determine whether full-day kindergarten enrollment is related to steeper growth in individual-specific achievement trajectories during the kindergarten year and to gain a more precise estimation of the duration of the full-day kindergarten advantage.

Research Goals

Individual differences in children's achievement trajectories, across the kindergarten year and beyond, stem from a unique constellation of child, school, home, and child-care characteristics (National Research Council and Institute of Medicine, 2000; Pianta, Rimm-Kaufman, & Cox, 1999). Guided by a developmental approach that highlights this heterogeneity and contextual embeddedness of children's lives, the aim of this study was to examine whether kindergarten program type explains individual differences in children's academic trajectories from kindergarten through fifth grade, net of salient aspects of children's home and child-care experiences. This study begins by providing a rich description and comparison of children attending full- and part-day kindergarten. Next, it considers whether full-day, as opposed to part-day, kindergarten attendance is linked with greater initial growth of reading and math skills during the kindergarten year after taking into account the influences of important characteristics of children's home and child-care settings. It then considers how long these benefits are sustained by examining trajectories of student achievement from the spring of kindergarten through the end of fifth grade.

Method

The data for this study come from the Early Childhood Longitudinal Study–Kindergarten Class of 1998–1999 (ECLS–K), a nationally representative cohort of children (U.S. Department of Education, National Center for Education Statistics, 2001). The ECLS–K was designed to study relations among children's developmental trajectories and their family, preschool, and school experiences. The sample was selected to be nationally representative of all children entering kindergarten in the fall of 1998 using a multistage probability sample design, where the primary sampling units (PSU) were geographic areas consisting of counties or groups of counties, the second-stage sampling units were schools within PSUs, and the final stage sampling units were students within schools. In total, nearly 22,000 kindergarteners throughout the United States participated in the study in the fall of 1998. The ECLS–K collected base-year data in the fall of kindergarten in 1998 and the spring of kindergarten in 1999. Four waves of data have been collected beyond the kindergarten year. These have taken place in the fall and spring of first grade, the spring of third grade, and the spring of fifth grade. The ECLS–K planned to collect data from all children at each wave of the study, with the exception of the fall of first grade, when data were collected only from a representative 30% of the entire sample of schools. Each school year of the survey information was collected from parents, teachers, and school administrators. Parent interviews were conducted by telephone or in person for families without a telephone, and teachers and school administrators were surveyed through self-administered questionnaires. The data were collected across several domains and include multimethod, multisource, in-school assessments of children's cognitive development as well as measures of family, school, and classroom characteristics that have been associated with children's development.

Sample

The sample that was used in this study consists of first-time kindergarteners who remained in the same type of kindergarten program (full or part day) throughout the kindergarten year, who were in kindergarten for at least 4 days per week, and who had at least one valid observation in reading and in math from kindergarten through fifth grade. Only children who had a valid sampling weight (C1PW0) were included in the sample. Altogether, 13,776 children were included in our sample. This represents 78% of the entire sample of children for whom ECLS–K recalibrated the item response theory score (IRT) assessment scores from kindergarten through fifth grade. The number of children dropped from our sample because of our exclusion criteria are as follows: children who repeated kindergarten ($n = 675$), those who switched program type ($n = 240$), those who were not in kindergarten for at least 4 days per week ($n = 389$), those who did not have a valid math or reading assessment ($n = 79$), and those with a sampling weight of 0 or missing weight ($n = 2{,}501$).

Of the 13,776 children included in the sample, 64% and 68% had valid reading and math scores, respectively, for five or six waves of data from the fall of kindergarten through the spring of fifth grade, and 31% and 29% had valid reading and math scores, respectively, for three or four waves of data. An extensive set of 17 covariates are included in our analyses that reflect important characteristics of children and their in-school and out-of-school contexts. Of the 13,776 children in our sample, 87% had valid data on all the 17 covariates. Statistical comparisons of children who had missing child assessments or important covariates showed that they were more disadvantaged across several dimensions. For example, they were more likely to be of an ethnic minority background, scored slightly lower on academic skills, and their parents tended to be less educated and to have incomes at or below the poverty line.

Traditional approaches to handling missing data, such as listwise deletion or mean imputation, have been criticized for biasing estimates, misrepresenting statistical power, and leading to invalid conclusions (Acock, 2005; Rubin, 1987; Widaman, 2006). Therefore, missing data were imputed for the present study using multiple imputation by chained equations (ICE), which was implemented in Stata (Royston, 2004). Multiple imputation was performed in Stata to create five complete data sets that included both the independent and the dependent variables in our models. The primary analysis for this study was performed using HLM 6.04 (Raudenbush, Bryk, Cheong, Congdon, & du Toit, 2004). Following imputation, the five data sets were imported into HLM, which was then used to conduct separate analysis for each set of plausible values. Based on the relative efficiency calculation by Rubin (1987), five multiple imputations were deemed sufficient. Parameter estimates were averaged and standard errors were computed in HLM 6.04 using standard techniques described by Raudenbush et al.

Measures

Academic achievement. Academic achievement in math and reading was measured in school using individualized, direct cognitive assessments designed by the ECLS–K. Several items on the assessment were adapted from existing instruments that have been shown to be reliable and valid measures of children's cognitive and academic development, such as the Woodcock–Johnson Psycho-Educational Battery, the Peabody Picture Vocabulary Test, and the Peabody Individual Achievement Test (Dunn & Dunn, 1981; Dunn & Markwardt, 1970; Markwardt, 1989; Woodcock & Mather, 1989, 1990). Both direct cognitive batteries have been shown to have good internal consistency. The reading assessment tests a broad range of children's language and literacy skills, including letter recognition, receptive vocabulary, and reading comprehension. Items on the mathematics assessment are aimed at measuring general mathematical skills, with questions on topics such as number sense, properties, measurement, and spatial sense.

An important prerequisite for growth modeling is to have an outcome variable measured on a consistent metric over time (Singer & Willett, 2003). To facilitate longitudinal analyses of children's academic achievement, the ECLS–K calculated IRT scores, which estimate children's performance as if they had been administered the whole set of assessment questions. The first set of IRT scores were created for children participating in the kindergarten and first-grade rounds of data collection. As children aged and the assessments were expanded in third and fifth grades, the ECLS–K recalibrated the IRT scores from all prior waves of data to make longitudinal comparisons possible (U.S. Department of Education, National Center for Education Statistics, 2005). Here, we used the recalibrated fifth-grade IRT scores, which is in keeping with prior studies of academic growth using the ECLS–K (e.g., Kaplan, 2002; McCoach, O'Connell, Reis, & Levitt, 2006; Ready, LoGerfo, Burkam, & Lee, 2005).

Kindergarten and school experiences. The primary independent variable of interest in these analyses is kindergarten program type, which is represented with a dichotomous indicator for whether children were enrolled in part- versus full-day kindergarten. Reports of children's kindergarten program type were obtained during interviews with kindergarten teachers. A teacher-reported indicator of whether a child changed teachers during the kindergarten year was included as well. Several basic school demographic characteristics were also included in these analyses, including school type, region, and urbanicity. School type was coded with a dummy variable that indicated whether children attended private versus public schools. The school's geographic location was modeled with dummy variables indicating whether the child lived in the Northeast (omitted from the model as the comparison group), Midwest, South, or West. Finally, schools' urbanicity was represented with variables indicating whether the schools were located in suburbs/large towns (omitted), central cities, or small towns/rural areas.

Out-of-school contexts. This investigation focused on four dimensions of out-of-school contexts: quality of cognitive stimulation in the home, household poverty, and type and extent of child care. First, parents were asked about several different types of learning activities that took place in children's home environments during a typical week. Items were adapted from reliable measures of children's home learning environments that have been widely used and validated in the literature, such as the Home Observation for Measurement of the Environment (HOME) Inventory (Caldwell & Bradley, 1979). For most items, parents rated the frequency with which children engaged in particular learning activities, such as reading books, singing songs, and listening to music, on a 4-point scale (1 = *not at all* and 4 = *3 to 6 times a week*). Dimensions of children's home learning environments that were measured by these items include the level of academic guidance and support provided to children; the degree to which children engaged in new activities and explored and discussed new ideas; and the amount of language stimulation children experienced. Factor analyses were performed to create a composite measure, which was calculated by taking a mean of 24 items asked in the fall and spring of kindergarten (α = .80). Second, family economic resources were represented with a dummy variable indicating whether or not children lived in households with incomes below the poverty line during kindergarten.

The third and fourth aspects of out-of-school contexts were type and extent of child care, which were measured during kindergarten and during the year prior to kindergarten. Prekindergarten type of care was represented categorically by dummy variables indicating whether children were in parental care (omitted), Head Start, other center care, relative care, nonrelative care, or multiple types of care. Type of care during kindergarten was modeled categorically by dummy variables reflecting whether children were in parental care (omitted), center care, relative care, nonrelative care, or multiple types of care. The average hours per week of care during kindergarten and the year prior to kindergarten were each represented continuously.

Family and child characteristics. Several family and individual characteristics that are important for children's developmental trajectories were included in these analyses to further test the robustness of the linkage between kindergarten program type and children's academic trajectories. All these measures were obtained during parental interviews in kindergarten. Parental education was represented categorically as the highest level of education attained by either parent. Categories include less than a high school diploma (omitted), a high school diploma, a vocational or technical program, bachelor's degree, and advanced degree. Maternal age at first birth was measured in years, and the number of children younger than 18 years living in the household was used as an estimate of parents' household caretaking responsibilities. Parental marital status was represented with dummy variables indicating whether parents were married (omitted), never married, separated/divorced, or widowed. Dummy variables were also included for children who lived with nonbiological or adoptive parents, and for whether a non-English language was the primary language spoken at home.

Finally, children's individual characteristics were obtained during parent interviews in kindergarten. Gender was represented with a dummy variable, and the age at which children started kindergarten was measured in months. Child race/ethnicity was represented with a series of dummy variables reflecting whether children were of a Hispanic, non-Hispanic Black, non-Hispanic White (omitted), non-Hispanic Asian, non-Hispanic Native American, or multiethnic background. An indicator of low birth weight was used to represent whether children weighed less than 5.5 pounds at birth.

Analytic Approach

Setting the stage for this investigation, we first sought to depict a national descriptive portrait of children attending full- versus part-day kindergarten. To test whether there were significant differences between these two groups of children, no constant regression analyses were performed, with the dummy indicator for kindergarten program type as the only independent variable, and achievement measures, family and child characteristics, and school demographic characteristics as dependent variables. When testing for differences in family and child characteristics that were represented categorically (e.g., race, parental education), each category was tested as a separate dependent variable to determine whether there were significant differences by kindergarten program type in the proportion of individuals falling into each particular category. This descriptive analysis was performed in Stata, with Huber–White standard error corrections (Huber, 1967) to take into account the nesting of children within schools, and sampling weights were applied.

Next, to examine whether there were initial and long-term benefits to attending full-day kindergarten, we estimated three-level models (Raudenbush & Bryk, 2002) in HLM 6.04 using full information maximum likelihood estimation and sampling weights

(Raudenbush et al., 2004). At Level 1 were children's achievement scores, which were nested within individual children at Level 2, who were nested within schools at Level 3. Children's academic trajectories were estimated using piecewise growth models. To consider whether full-day kindergarten was initially beneficial to the growth of children's academic skills during the kindergarten year, the first trajectory measured growth from the fall of kindergarten to the spring of kindergarten. To examine how long these initial benefits to achievement growth were sustained, the second trajectory measured growth from the spring of kindergarten to the spring of fifth grade. The form of the Level 1 equation can be seen in Equation 1:

$$Y_{tij} = \pi_{0ij} + \pi_{1ij}\text{Time 1}_{tij} + \pi_{2ij}\text{Time2}_{tij} + \varepsilon_{tij}. \qquad (1)$$

We created Time 1 and Time 2 to track growth across kindergarten and from the spring of kindergarten through the spring of fifth grade, respectively. The time of each assessment was measured as the number of months that had passed since September 1, 1998, because the exact start of the school year was not available in the public release data. There was great variability in the month in which each of the assessments took place; for example, the fall of kindergarten assessments took place between September and December. Therefore, the exact number of months that had passed at the time of the assessment was used to yield greater precision in estimating the growth trajectories. The Time 1 variable was centered at the time of the fall kindergarten assessment, and the Time 2 variable was centered at the time of the assessment at the spring of kindergarten. Thus, academic achievement at time *t* for child *i* in school *j* was modeled as a function of the academic achievement of child *i* in school *j* at the fall of kindergarten (π_{0ij}), his or her per month growth of achievement skills during the kindergarten year (π_{1ij}), and his or her monthly growth rate from the spring of kindergarten until the spring of fifth grade (π_{2ij}).

We began our growth trajectory analyses by estimating unconditional growth models, with the coefficients on the slopes in the Level 1 equation estimated as random. The Level 1 intercept and Level 2 intercept predicting the Level 1 intercept were fixed due to model convergence problems (Dearing et al., 2001). The remaining intercepts of the Level 2 equations were estimated as random, and the slope coefficients of the Level 2 equations were fixed at Level 3.

After finding significant variability in the Level 1 and Level 2 parameters, conditional models were estimated to explain the heterogeneity in trajectories of academic achievement.

Equations 2 through 4 were used at Level 2 to model variability in the Level 1 parameters:

$$\pi_{0i} = \beta_{00j} + \beta_{01j}\text{KT}_{ij} + \beta_{02j}\text{FT}_{ij} + \beta_{03j}C_{ij} + \beta_{04j}F_{ij} + \beta_{05j}\text{CCPK}_{ij} + \beta_{06j}\text{CCK}_{ij} \qquad (2)$$

$$\pi_{1ij} = \beta_{10j} + \beta_{11j}\text{KT}_{ij} + \beta_{12j}\text{FT}_{ij} + \beta_{13j}C_{ij} + \beta_{14j}F_{ij} + \beta_{15j}\text{CCK}_{ij} + r_{1ij} \qquad (3)$$

$$\pi_{2ij} = \beta_{20j} + \beta_{21j}\text{KT}_{ij} + \beta_{22j}\text{FT}_{ij} + \beta_{23j}C_{ij} + \beta_{24j}F_{ij} + r_{2ij}. \qquad (4)$$

Here, the initial level of academic achievement was modeled as a function of kindergarten program type (KT_{ij}), and a series of child (C_{ij}), family (F_{ij}), prekindergarten child care (CCPK_{ij}), and kindergarten child-care (CCK_{ij}) characteristics. The time of the child assessment at the fall of kindergarten (FT_{ij}) was included as a predictor as well because children who were assessed later in the school year tended to have more advanced academic skills than did those who were assessed earlier. All independent variables in the Level 2 equation for the intercept were measured in kindergarten. The two slope parameters were estimated as a function of this same set of independent variables, with the exception that only child-care characteristics in kindergarten were used to predict the kindergarten slope. Also, no child-care characteristics were used to model variability in the coefficient on Time 2 because child-care experiences are less relevant in predicting achievement growth after children are in school full time. Except for the indicator for kindergarten program type (KT_k), which was coded as 1 for part-day programs and 0 for full-day programs, all independent variables at Level 2 were centered on the grand mean for the sample, so that the intercepts at Level 2 represent adjusted means for the average study participant in full-day kindergarten (Raudenbush & Bryk, 2002).

At Level 3, we introduced a set of school-level demographic characteristics. Equations 5 through 7 were used to predict the Level 2 intercepts:

$$\beta_{00j} = \gamma_{000} + \gamma_{001}\text{ST}_j + \gamma_{002}R_j + \gamma_{003}U_j \qquad (5)$$

$$\beta_{10j} = \gamma_{100} + \gamma_{101}\text{ST}_j + \gamma_{102}R_j + \gamma_{103}U_j + u_{10j} \qquad (6)$$

$$\beta_{20j} = \gamma_{200} + \gamma_{201}\text{ST}_j + \gamma_{202}R_j + \gamma_{203}U_j + u_{20j}. \qquad (7)$$

Specifically, school type (ST), geographical region (*R*), and urbanicity (*U*) were used to model the intercepts of the Level 2 equations. However, the Level 2 slope coefficients were fixed at Level 3 and did not include any predictors because we had no a priori hypotheses about how school characteristics would moderate the influence of the Level 2 independent variables.

The conditional growth models were built in three steps. In the first model, academic growth trajectories at Level 1 were estimated as a function of whether children attended part-day kindergarten at Level 2. In the second model, important characteristics of children's out-of-school contexts were taken into account, with quality of cognitive stimulation in the home, household poverty status, and type and extent of child care added as covariates at Level 2. In the third and final model, other family and child characteristics were included at Level 2 and school characteristics added at Level 3 as an additional test of the robustness of the association between kindergarten program type and children's achievement trajectories.

Results

Are There Significant Differences Between Children Attending Full- Versus Part-Day Kindergarten?

Laying the groundwork for our multivariate analyses, we first consider whether significant differences exist between students enrolled in part- and full-day kindergarten. Descriptive information for the sample as a whole as well as for subgroups of children by program type can be found in Table 1. As shown in the top row, 45% ($n = 6{,}202$) of children were enrolled in part-day kindergarten and 55% ($n = 7{,}574$) in full-day kindergarten.

Regarding family and household characteristics, the poverty rate among part-day kindergarten students was 6% lower than that for full-day kindergarten students. Among part-day kindergarten students, the highest level of parental education was slightly greater, the proportion of children from married parent households was higher, and the percentage of children from households with parents who had never been married was lower. Not surprisingly, based on these socioeconomic differences, the quality of cognitive stimulation in the home environments of part-day kindergarten students was about one tenth of 1 *SD* higher than that of their peers. A greater percentage of children in part-day kindergarten (14%) versus full-day kindergarten (9.8%) came from a non-English-speaking household.

Moving on to child care, part- and full-day kindergarteners had different experiences during kindergarten. Children attending part-day kindergarten programs spent more hours in child care, had a higher likelihood of receiving nonrelative home-based child care, and had a lower likelihood of receiving relative home-based child care. In contrast, during the year prior to kindergarten, children in part- and full-day kindergarten had somewhat similar child-care experiences. However, part-day kindergarteners spent about 6 hr less in nonparental care per week, were less likely to have attended Head Start, and more likely to be cared for in a nonrelative home-based child-care setting, when compared to full-day kindergarten students.

In addition to contextual differences, children enrolled in part- versus full-day programs varied in terms of their individual characteristics. The most notable of these differences was in the racial composition of the two groups of children. More specifically, a greater proportion of children in part-day kindergarten were of Hispanic, non-Hispanic White, Asian, and multiracial backgrounds, and a smaller proportion were of non-Hispanic Black and Native American race/ethnicity, in comparison to full-day kindergarteners. These differences were moderate to large in magnitude. For example, 7% of part-day kindergarteners were of non-Hispanic Black ethnicity, whereas 22% of full-day kindergarteners fell into this category. Children in part-day kindergarten entered school when they were slightly younger and less likely to have been of low birth weight compared to children in full-day kindergarten. There were no significant differences in child gender by program type.

Furthermore, children's mean levels of academic achievement at the fall of kindergarten did not differ significantly. By the spring of kindergarten, the math skills of the two groups of children were statistically indistinguishable. Still, children in full-day kindergarten outscored their part-day kindergarten counterparts in reading by one tenth of 1 *SD*. By the fall of first grade, children's achievement did not vary across program type and remained similar, until the spring of third grade, when part-day kindergarteners outscored full-day kindergarteners on the math and reading skills measures by one tenth of 1 *SD*. This disparity grew slightly in the spring of fifth grade. Finally, there were several significant differences in school characteristics by kindergarten program type. For example, a greater proportion of children in full-day kindergarten (54.7%) versus part-day kindergarten (14.1%) attended schools located in the South, whereas a lower proportion of full-day kindergarteners attended schools located in the West, Northeast, and Midwest. Full-day kindergarteners also had somewhat higher rates of private versus

public school enrollment when compared to part-day kindergartener students. In sum, several differences emerged between children attending full- and part-day kindergarten; however, when differences were detected, they tended to be modest in magnitude.

Does Attending Full-Day Kindergarten Yield Benefits to Children's Academic Achievement?

Moving on to our analyses of children's academic trajectories, we estimated math and reading trajectories from the fall of kindergarten until the spring of fifth grade, in order to address the question of whether full-day kindergarten attendance explained variability in children's development. We began by estimating unconditional growth models, which are given in Table 2. Here, it can be seen that the math and reading scores for the average child in the sample at the fall of kindergarten were 23.155 and 29.372, respectively. Examining the coefficients on the two slope terms, it can be seen that the slopes of children's achievement trajectories were somewhat steeper between the fall and the spring of kindergarten, compared to the slopes of trajectories between the spring of kindergarten and fifth grade. The two slope terms in the unconditional growth models were correlated .80 for math and .66 for reading. Chi-square tests revealed that there was significant variability between individuals' achievement trajectories.

Given that children were heterogeneous in their academic trajectories, we next estimated conditional models of student achievement trajectories from the fall of kindergarten to the spring of fifth grade, with results for math displayed in Table 3 and findings for reading shown in Table 4. In Model 1 of Tables 3 and 4, an indicator of part-day kindergarten was used to predict the intercepts and slopes of children's achievement trajectories. Consistent with the descriptive analysis, there were no significant differences related to kindergarten program type at the fall of kindergarten, as indicated in Panel A. However, as shown in Panel B, the coefficients on the part-day indicator for the first slope in the piecewise growth models show that from fall to spring of the kindergarten year, the math and reading skills trajectories of children in part-day kindergarten were characterized by slightly slower rates of growth. More specifically, the math and reading skills of the average child in

part-day kindergarten grew by 2.189 and 2.632 per month, respectively, whereas the respective growth rates for full-day kindergarteners were 2.435 and 2.930. By the end of the kindergarten year, children in full-day kindergarten outscored part-day kindergarteners by one fifth of 1 *SD* in math and reading.

To consider whether the benefits of full-day kindergarten are sustained through the spring of fifth grade, we examined the coefficients on the second slope term in our piecewise growth models, which are found in Panel C of Model 1 of Tables 3 and 4. These suggest that the initial benefits of full-day kindergarten for the growth of achievement trajectories were not sustained beyond the kindergarten year. Indeed, the positive and significant coefficients on the part-day indicators for the second slope coefficients suggest that from the spring of kindergarten through fifth grade, the academic skills of children in part-day kindergarten grew at a slightly faster rate than did those of children in full-day kindergarten. Figure 1 illustrates the reading growth curve trajectories of children by kindergarten program type from the fall of kindergarten through the spring of third grade based on this first conditional model. The plot of children's math skills looks nearly identical. Here, it can be seen that although full-day kindergarten was associated with a small academic advantage across the kindergarten year, the achievement trajectories of children in part- and full-day kindergarten converge soon after children leave kindergarten. Indeed, Figure 1 shows that the advantage of full- versus part-day kindergarten has faded out by the spring of third grade, with the two groups diverging and the part-day kindergarteners pulling ahead. Though not shown here for parsimony, the divergence continues into the spring of fifth grade.

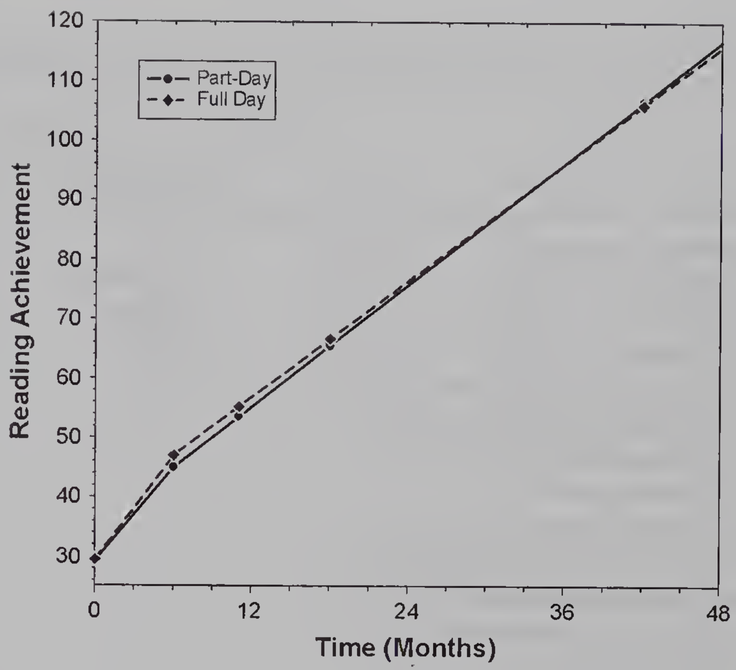

Figure 1. Kindergarten program type and reading achievement trajectories from fall of kindergarten to spring of third grade.

In Model 2 of Tables 3 and 4, measures of children's out-of-school contexts were introduced, including the quality of cognitive stimulation in the home environment, household poverty status, and the type and extent of nonparental care during kindergarten and the year before kindergarten entry. These factors were significantly related to children's achievement in the fall of kindergarten. More specifically, children who experienced high-quality home environments and nonparental care in the year before kindergarten (with the exception of Head Start enrollment), and those from nonpoor households tended to start school with higher levels of reading and math skills. The introduction of these variables as predictors of the intercept revealed a significant difference in achievement between children in part- and full-day kindergarten that favored full-day kindergarten students, though this association was only marginally significant for math achievement.

The inclusion of this important set of variables as predictors of the kindergarten slope term resulted in a 26% and 19% reduction in the association between kindergarten program type and children's math and reading skills trajectories, respectively, during the kindergarten year, highlighting the importance of these contexts for children's development. Together, cognitive stimulation in the home environment and the poverty status of the child's household were responsible for a modest decrease in the magnitude of the part-day coefficient. More specifically, the math and reading skills of children from impoverished households grew at slower rates than did those of children in households above the federal poverty

threshold, whereas the achievement trajectories of children from more stimulating home environments increased at steeper rates during the kindergarten year. After taking these differences into account, the disadvantage of attending part-day kindergarten appeared modestly smaller. Contrary to our hypothesis, kindergarten child-care characteristics did not emerge as significant predictors of achievement trajectories during the kindergarten year.

The introduction of out-of-school contexts also slightly decreased the part-day kindergarten advantage for children's achievement trajectories from the spring of kindergarten to the spring of fifth grade. Indeed, the coefficient on the part-day kindergarten indicator for the second slope of children's math and reading trajectories fell by about 9% with the introduction of the additional measures into the analysis. Again, cognitive stimulation in the home environment and family poverty status were responsible for this reduction. This suggests that the convergence of the achievement trajectories of children in part- and full-day kindergarten may in part be explained by the lower levels of poverty and the more stimulating home environments of children enrolled in part-day, as opposed to full-day kindergarten programs. Based on this second set of conditional models, it can be anticipated that by the end of the kindergarten year, children in full-day kindergarten outscored part-day kindergarteners by 0.11 of 1 *SD* for math and 0.15 of 1 *SD* for reading, which is one half to one quarter of a reduction in the expected gain based on the first set of conditional models.

In Model 3 of Tables 3 and 4, an extensive set of potentially confounding factors were added as predictors of children's achievement trajectories, with child and family characteristics added to the Level 2 equations and school characteristics added at Level 3. The introduction of this comprehensive set of control variables resulted in slight increases in the association between kindergarten program type and academic achievement at the fall of kindergarten. More importantly, however, it led to further reduction of the benefit of full-day kindergarten for the growth of academic skills during kindergarten. Indeed, the part-day kindergarten coefficients on the kindergarten slope terms in the prior conditional models decreased 16% and 8% for math and reading, respectively. The quality of children's home environment and their household poverty status continued to be significantly associated with achievement trajectories during kindergarten, though the sizes of these coefficients dropped with the inclusion of the more comprehensive set of

covariates. The introduction of this extensive set of covariates in Model 3 of Tables 3 and 4 further attenuated the association between kindergarten program type and achievement trajectories from the spring of kindergarten to fifth grade as well. Indeed, compared to Model 2, 36% of the part-day growth advantage in math and 17% of the part-day growth advantage for reading were explained by this set of covariates. Although child poverty continued to be significantly related to the second slope term, cognitive stimulation in the home environment was no longer a significant predictor. Thus, it appears that differences in poverty status, not cognitive stimulation in the home environment, may be responsible for explaining the part-day kindergarten advantage in academic growth from the spring of kindergarten through fifth grade.

Discussion

Full-day kindergarten experiences are becoming increasingly common for children across the United States. Yet, there are notable gaps in the literature regarding whether full-day kindergarten attendance is advantageous for children's development. This is the first study to take a developmental approach to examining the implications of full- versus part-day kindergarten for children's learning trajectories. Specifically, this investigation recognizes both the heterogeneity of children's achievement trajectories and the complex configuration of child, family, and nonparental care factors that affect their developmental trajectories. In doing so, this study provides important insights about the size and persistence of the full-day kindergarten advantage and strengthens our understanding of when and why the full-day kindergarten advantage seems to fade out soon after the end of the kindergarten year.

Full- Versus Part-Day Kindergarteners: A Descriptive Portrait

Our descriptive portrayal of a nationally representative sample of kindergarteners revealed several significant, but generally modest, differences in out-of-school dimensions and individual characteristics of children in part- versus full-day kindergarten programs. Among the most notable difference is the racial composition of the two groups of children. More specifically, a greater proportion of children in part-day kindergarten were of Hispanic, non-Hispanic White, Asian, and multiracial backgrounds, and a smaller proportion were of non-Hispanic Black and Native American race/ethnicity, in comparison to full-day kindergarteners. The largest difference when it came to racial composition was in the proportion of children of non-Hispanic Black ethnicity in each group. This proportion was three times higher among full-day kindergarteners (22%) when compared to part-day kindergarten students (7%). On the whole, the bivariate analysis suggests that part-day kindergarteners were more advantaged socioeconomically; however, the multivariate analyses that controlled for these differences surprisingly revealed higher levels of academic achievement at the fall of kindergarten among children enrolled in *full*-day kindergarten. Future research that more carefully models families' selection of full- versus part-day programs for their children is needed to untangle the more complex story detected here.

Benefits of Full-Day Kindergarten Attendance During the Transition to School

The results of this study concur with the existing body of research that has largely shown significant academic benefits of full- versus part-day kindergarten programs (e.g., Cannon, Jacknowitz, & Painter, 2006; Clark & Kirk, 2000; Gullo, 2000; Kaplan, 2002; Lee et al., 2006; Walston & West, 2004; Weiss & Offenberg, 2002). Unlike prior studies, however, the current investigation linked kindergarten program type not only to levels of academic achievement but also to individual growth trajectories of students' math and reading skills during the kindergarten year using data from a nationally representative study. Without controls for important child, family, and nonparental care characteristics, full-day kindergarten students' achievement grew at a rate that was 0.246 points per month faster in math and 0.298 points per month faster in reading. This amounted to a modest advantage in math and reading achievement, which was roughly one fifth of 1 *SD*. After an extensive set of child, family, school, and nonparental care characteristics were introduced to the growth models, the magnitude of the full-day kindergarten advantage dropped in half for math and by one quarter for reading, resulting in estimates of the full-day kindergarten advantage that are quite small and are similar to those found by Cannon et al. (2006) with these same data.

The modest nature of the full-day advantage may be attributed to slight differences in the amount and type of instruction taking place in kindergarten classrooms. Although teachers participating in the ECLS-K report that full-day kindergarteners spent roughly two times as much time in school as half-day kindergarteners, they did not receive two times as much instruction (Xue, Burkam, & Lee, 2002). For example, full-day kindergarten teachers spend 5.5 hr per week in reading and language arts and 3.7 hr in mathematics, whereas part-day kindergarten teachers spend 4.3 hr in reading and language arts and 2.5 hr in mathematics (Xue et al., 2002). Furthermore, full- and part-day classes are organized in similar ways, in terms of the proportion of time spent in whole class, small group, individual, and child-selected activities (Walston & West, 2002). Additional research on the heterogeneity of instructional practices and of teacher – child interactions that occur within part- and full-day kindergarten programs may help identify whether characteristics of kindergarten beyond program type are more successful in promoting student achievement.

Fading Benefits of Full-Day Kindergarten Attendance During Early Elementary School

Perhaps the most troubling finding of the present study is that the academic benefits of full-day kindergarten subside soon after children leave kindergarten. This is congruent with past research that has found that the academic benefits of full-day kindergarten are relatively short lived (Karweit, 1987; Ohio State Legislative Office of Education, 1997; Weiss & Offenberg, 2002). Unlike prior research, this developmental approach paints a more nuanced understanding of the fade-out of the full-day kindergarten advantage, both by providing a more precise estimate of when the fade-out occurs and by shedding light on factors that are partially responsible for explaining why the trajectories of children in part- and full-day kindergarten converge. The fade-out occurs as the trajectories of children in part-day kindergarten grow at a steeper rate from the spring of kindergarten to the spring of fifth grade. Our models suggest that the advantage of full- versus part-day kindergarten fades out approximately 36 months after the spring of kindergarten assessment, or in the spring of third grade. Furthermore, the fade-out appears to be attributed to differences in the children and families that attend part- and full-day kindergarten, as well as school characteristics associated with kindergarten program type. These differences explained 42% of the part-day kindergarten growth advantage in math from the spring of kindergarten through the spring of fifth grade and 25% of the part-day growth advantage for reading. Thus, it seems that the greater selection of children from, for example, economically disadvantaged households and a non-Hispanic Black ethnic background contributes to the fade-out of the full-day kindergarten advantage after the end of the kindergarten year. It is important to recognize, however, that this study is not able to rule out the threat of omitted variable bias when examining the fade-out of the full-day kindergarten advantage during the early elementary school years. Indeed, we are not able to rule out the possibility that it may be an unmeasured characteristic of parents or children that jointly explain families' home environment quality and economic status, which seem to be important in explaining the fade-out of the full-day kindergarten advantage.

Furthermore, this study fell short of entirely explaining why the growth rates of children attending part-day kindergarten programs tend to catch up to their full-day kindergarten counterparts so quickly. Other factors, such as subsequent schooling experiences, may be at play. Research on Head Start programs, the federally funded early childhood education intervention for economically disadvantaged children, lends support for this hypothesis. Lee and Loeb (1995) as well as Currie and Thomas (2000) found that differences in the schooling experiences subsequent to Head Start participation are important for understanding why Head Start effects seem to fade out over time. For example, using data from the National Education Longitudinal Study of 1988, Lee and Loeb found that children who attended Head Start were educated in schools of significantly lower quality, defined by social composition, academic rigor, safety, and social relations, when compared to counterparts who did not attend preschool and especially when compared to peers who attended other preschools. Similarly, more socioeconomically disadvantaged full-day kindergarten students may be attending schools of lower quality compared to the quality of schools attended by part-day kindergarteners. In other words, differences in children's later schooling experiences may erode the benefits associated with both Head Start and full-day kindergarten participation.

Policy Implications

Though it is impossible to reduce the threats of selection or omitted variable bias entirely with nonexperimental data, the results of this study suggest that the shift from part- to full-day kindergarten programs occurring across the United States may have positive implications for students' learning trajectories, at least in the short run. Here, we find modest but meaningful differences in the achievement trajectories of full- and part-day kindergarten students that favor full-day kindergarten programs. What is perhaps most concerning is the immediate nature of these benefits, which raises questions about whether the cost of full-day as opposed to part-day kindergarten programs is associated with sufficient benefits for children and society.

It is difficult based on the existing literature to determine the cost of full-day kindergarten programs. Cost estimates range substantially, even within the same state. According to Weiss and Offenberg (2002), who have conducted a cost–benefit analysis of full-day kindergarten in the School District of Philadelphia, the cost of full-day kindergarten is approximately $2,300 per year per child. Yet, the Pennsylvania Partnerships for Children (2000) estimated the median instructional expense of full-day kindergarten per pupil to be $5,216. A comprehensive cost–benefit analysis would be required to evaluate the relative effectiveness of public investments in full-day kindergarten as opposed to investment in other programs for children. To carefully conduct such an analysis, it would be important to look at other domains of student functioning in addition to academic achievement, such as measures of socioemotional functioning and physical health and well-being. Of course, the other rather obvious benefit of full-day kindergarten that must be taken into account in a systematic analysis is its linkage with parental employment. Cannon et al. (2006) found that mothers are more likely to work full time in the kindergarten year if their children attend full-day kindergarten. Increases in parental employment benefit society with higher tax revenue and can boost families' household income. It may be that these benefits end up being more important in making the case for full-day kindergarten in the policy arena than are achievement gains made by full-day kindergarteners. Although the present study provides useful information about associations between kindergarten program type and two domains of achievement, a more systematic accounting of the costs and benefits of the program, similar to what has been conducted for the Perry Preschool Project (Barnett, 1996; Belfield, Nores, Barnett, & Schweinhart, 2006), is necessary to evaluate public investments in full-day kindergarten.

Conclusions

In sum, this study advances the literature on full- versus part-day kindergarten attendance by situating such programs in a developmental context. Unlike prior studies in this research area, we recognized individual differences in children's achievement trajectories as well as the constellation of child characteristics, family factors, and nonparental care experiences that add nuance and texture to children's lives. In doing so, this study moved beyond static views of children's achievement and revealed that attending full-day kindergarten yielded a modest benefit to children's academic trajectories over time. Furthermore, our developmental approach highlighted the importance of considering not only whether children attending full-day programs were able to sustain these benefits but also when children enrolled in full-day programs no longer maintained this advantage. Here, we pinpointed that academic benefits associated with full-day kindergarten program attendance faded out by the end of the primary grades. Last, our developmental view brought children's background characteristics and experiences into the "foreground" of understanding differences between children attending full- versus part-day kindergarten programs. In focusing on the multifaceted nature of children's lives, we found that child and family characteristics played noteworthy roles in why full-day benefits exist and in why these advantages fade relatively quickly. Incorporating a developmental perspective into future studies of policies relevant to young children's educational experiences may similarly prove fruitful.

When can children speaking Japanese, English, or Chinese map and extend novel nouns and verbs? Across 6 studies, 3- and 5-year-old children in all 3 languages map and extend novel nouns more readily than novel verbs. This finding prevails even in languages like Chinese and Japanese that are assumed to be verb-friendly languages (e.g., T. Tardif, 1996). The results also suggest that the input language uniquely shapes verb learning such that English-speaking children require grammatical support to learn verbs, whereas Chinese children require pragmatic as well as grammatical support. This research bears on how universally shared cognitive factors and language-specific linguistic factors interact in lexical development.

Understanding how children learn nouns and verbs is crucial for our understanding of lexical development. Nouns typically designate objects that are visually stable across time and are individuated from the environment. In contrast, verbs typically denote actions that are more ephemeral and more difficult to individuate than objects. How do children learn nouns and verbs in the face of these conceptual differences?

This question is deeply related to the issue of whether noun learning is favored over verb learning across languages. Gentner (1982) proposed that nouns are easier to learn than verbs independent of the structural and distributional properties of the native language. However, this proposal has been challenged by results showing that early lexicons may contain equal numbers of nouns and verbs if verbs predominate in the input (e.g., Choi & Gopnik, 1995; Tardif, 1996). In languages including Chinese, Korean, and Japanese, both subjects and objects are often dropped from the sentence, having the effect of making verbs more prevalent in the input. Importantly, verbs appear more frequently than nouns in the maternal input (e.g., Choi & Gopnik, 1995; Kim, McGregor, & Thompson, 2000; Ogura, 2001; Tardif, 1996).

The question of whether Chinese, Korean, and Japanese children learn verbs earlier or at the same time as nouns is far from settled as mixed results have been reported. Some studies suggest that verbs predominate in the early production vocabularies of

Mandarin- and Korean-speaking children (Choi, 2000; Tardif, 1996). Other studies report approximately equal proportions of nouns and verbs (Choi & Gopnik, 1995). Still other studies note that the proportion of nouns is *higher* than verbs in Korean (Au, Dapretto, & Song, 1994; Bornstein & Cote, 2004; Kim et al., 2000) and in Japanese (Ogura, 2001; Yamashita, 1997) children's vocabularies.

Given the results reported in the literature, the issue of noun – verb dominance remains open. Additional investigations of some of the "verb-friendly" languages such as Navaho (Gentner & Boroditsky, 2005) and Tzeltal (Brown, Gentner, & Braun, 2005) as well as microlevel analyses of Chinese children's noun and verb vocabulary through different periods of lexical development are underway (Tardif, 2006). Nevertheless, a different approach is needed to corroborate the research using the checklists or corpus data because data from these methodologies have limitations.

Checklist and Corpus Data: Limitations

Methods of data collection that involve checklists and corpora provide us with rich and important information on the nature of early vocabularies. At the same time, each of these methods raises a number of issues that need to be addressed. First, context matters for corpus data. In studies using production data, the relative proportion of nouns and verbs in children's early vocabulary is taken to be an index of the relative difficulty of noun and verb learning. However, the relative proportion of nouns and verbs varies depending on the context in which the production data are collected even within a single language (Choi, 2000, Ogura, 2001; Tardif, Gelman, & Xu, 1999). For example, Japanese mothers produced more verbs in a toy-play context, whereas more nouns were produced in a picture book reading context (Ogura, 2001). Thus, samples collected in different contexts may yield different results.

Second, what counts as a "word" may differ across languages, and this may influence the number of nouns and verbs appearing on checklists or coded from production data. This problem influences the count for verbs more than for nouns because verbs tend to be more polysemous and crosslinguistically variable in their meanings (e.g., Gentner, 1982). For example, 开 (kāi) is a monosyllable verb in Chinese. Its meaning includes the rough equivalent of "to open," "to start," "to operate/drive," and "to release," among others. Even though 开 has its own entry as a verb in Chinese dictionaries, Chinese dictionaries usually list each word combination as a separate lexical entry (e.g., 开门 (kāimén) "open (a/the) door," 开会 (kāihuì) "have (a/the) meeting," 开车 (kāiche) "to drive"). In contrast, in English, although frequent verbs such as "run" and "take" are also polysemous, English speakers do not consider different senses of these words to be different lexical items. Thus, in constructing a checklist inventory in English, a polysemous verb is usually listed only once as a single lexical item.

Third, the use of a word (as indicated on a checklist or in production) does not guarantee full mastery of the meaning of the word. Children may use a particular word in a particular situation appropriately, but the total number of situations in which they could use the word appropriately may be much more limited than situations in which the word is used by adults (Bowerman, 1980; Dromi, 1987). For example, a child may use the verb "throw" when she sees someone throwing a ball, but she may not fully understand that one can throw any object that can be held with one's hand and one can throw things in many different ways (e.g., with two hands or one hand, underhand, or overhand, etc.; Forbes & Poulin-Dubois, 1997; see also Huttenlocher, Smiley, & Charney, 1983). Thus, although the age of an entry on a checklist or in production has been a popular measure of acquisition of word meaning, it may take a long time for children to acquire an adult-like understanding of the meaning of a word after it is first entered in the child's vocabulary (Theakston, Lieven, Pine, & Rowland, 2002).

Considering these issues, it is difficult to conclusively determine whether nouns or verbs are learned more "easily" based on the checklist and production data alone. Furthermore, characterizing noun and verb learning along the dimension of "ease/difficulty" of learning may not be the best way to deepen our understanding of the *nature* of the early lexicon and of the *mechanisms* that undergird early lexical development.

Here, we investigate the nature of early noun and verb learning from a different perspective. Specifically, we ask whether children from three different language groups are able to map and extend novel nouns and novel verbs, and how conceptual differences between nouns and verbs interact with the linguistic and distributional properties of a target language. Using a laboratory-based, novel word-learning paradigm, we supplement what is known about the process involved in the learning of novel nouns and verbs. Importantly, this is a different (and perhaps complimentary) way to approach these issues as both checklists and production data assess words that are already evident to some extent in children's vocabulary. Studying how readily young children from three language groups map and extend novel nouns and verbs adds a new dimension to our understanding of the mechanisms that support word learning and to how a child's native language interacts with these mechanisms.

Mapping and Extending Novel Nouns and Verbs

Tests of word extension (e.g., knowing that a cup refers to more than the original cup) clarify the construal children give for a particular lexical item. For example, if extension is inappropriately limited, it suggests that children have an overly narrow meaning for the novel word that might be limited to a particular context. Further, names for objects are often generalized on the basis of the sameness of shape (Imai, Gentner, & Uchida, 1994; Landau, Smith, & Jones, 1988). Names of substances (like sand and water), however, must be generalized on the basis of the sameness of the material alone. Temporary configuration of the substance is irrelevant for generalization (Imai & Gentner, 1997; Imai & Mazuka, 2003, 2007; Soja, Carey, & Spelke, 1991). The meaning of a noun—whether it is a name of an object or of a substance—is independent of how the referent entity is acted upon. A ball is a ball whether it is thrown, kicked, rolled, etc.

Verbs are extended to categories of relations. An action can be done with many different objects. We can throw a ball, a Frisbee, a stone, a disk, or almost anything we can lift up with our hands. Thus, in generalizing a verb, children need to align relevant components of action events, compare across different scenes, and focus only on the sameness of the higher order relation between the objects while ignoring the sameness of the objects (Imai, Haryu, & Okada, 2005).

How do children map novel nouns and verbs onto nonlinguistic conceptual categories? Childers and Tomasello (2002) examined whether 2-year-old English-speaking children appreciate both the noun–object link and the verb–action link. They showed 2.5-year-old English-speaking children three different novel objects and taught their noun labels. In another condition, they demonstrated three novel actions performed with three novel objects and taught three novel verbs corresponding to the three actions. Their results indicated that children learned the noun–object link more readily than the verb–action link. Their study, however, did not ask how children extend novel nouns and verbs.

Golinkoff, Hirsh-Pasek, Bailey, and Wenger (1992) and Golinkoff, Jacquet, Hirsh-Pasek, and Nandakumar (1996) studied fast-mapping and extension of novel nouns and verbs. In the first study with nouns (Golinkoff et al., 1992), children were asked to select a novel object amid three familiar objects when it was requested with a novel noun. On the next trial, they were asked to extend the novel noun, selecting from among two familiar exemplars (e.g., a shoe and a block), another novel exemplar, and the original exemplar in another color. At 28 months, children could learn and extend a novel noun in this task. Using cards with Sesame Street characters depicting familiar and novel actions, it took an additional 6 months for young children to learn and extend novel verbs (Golinkoff et al., 1996).

Imai et al. (2005) asked how Japanese children differentially learn and extend nouns and verbs. Imai et al. showed a video of an action event involving a woman, a novel action, and a novel object. Half of the children heard a novel noun, and the remaining children heard a novel verb while they were watching the video. The children were presented with two variants of the standard event: In one, the same woman was doing the same action with a different object; in the other, the same woman was doing a different action with the same object as the standard event. Children were asked to indicate to which scene the word (the newly introduced noun or verb) would apply. Both 3- and 5-year-olds successfully mapped a novel noun to an object, generalizing it to the same object used in a different action. In stark contrast, only 5-year-olds, but not 3-year-olds, showed understanding that verbs are extended on the basis of the sameness of actions and the objects are variables that can be changed across different events (see Kersten & Smith, 2002, for converging results with English-speaking children).

These studies suggest that children more readily map and extend novel nouns than novel verbs. However, none of these studies included a comparison across different language groups. A crucial issue for our understanding of the nature of early lexical development is how word learning interacts with the nature of the language children are learning. It is thus extremely important for us to consider how children's performance in novel noun and verb learning in the same experimental settings interacts with linguistic and distributional properties of their language.

Comparing Word Learning Across Languages: The Present Research

Comparing children learning English, Japanese, and Chinese is theoretically interesting because the three languages differ from one another on dimensions thought to affect the relative difficulty of verb learning. One dimension on which the languages differ is whether they allow argument dropping in the production of the sentence. In Japanese and Chinese, verb arguments are frequently dropped (e.g., the nouns surrounding the verbs are not expressed). In fact, in Japanese, when the speaker thinks that the hearer can infer the arguments from the context, as a default, the arguments are dropped. This means that, in Japanese and Chinese, it is possible that a verb is the only word in the sentence. For example, when you see someone drop a wallet from her purse, in Japanese, you are likely to say "otoshi (drop)-mashi (honorific)-ta (past)-yo (emphatic sentence-final particle)" "(you) dropped (it)." Here, the subject and the object of the sentence are both omitted. In English, this kind of argument dropping virtually never occurs.

The second dimension on which the languages differ is in the presence of morphological inflection as in verbs. Here, Chinese contrasts with not only English but also with Japanese. Although verbs conjugate in both English and Japanese, they do not in Chinese. Thus, nouns and verbs are not *morphologically* distinguished in Chinese (Erbaugh, 1992). In Chinese and Japanese, where verb arguments are often dropped, the verb alone can constitute a sentence in the utterance. In Japanese, even when this occurs, verbs can be identified by inflectional morphology. That is, when a verb is produced without the arguments, as in "Mite (Look), X-teiru (X-ing)," one can tell by the presence of the "teiru" ending that the word X is a verb. However, in Chinese, when a word is produced on its own (and this happens occasionally in conversational discourse), it is difficult to tell whether it is a noun or a verb (Li, Jin, & Tan, 2004). A novel word can be identified as a verb *only when* it is embedded in the argument structure of the prior discourse (see Li, Bates, & MacWinney, 1993, for discussion of how Chinese-speaking adults determine grammatical classes in sentence processing).

This research extends Imai et al.'s (2005) study to examine two questions. First, we probe whether the noun advantage found in Imai et al.'s (2005) study holds across children learning very different languages. Second, we ask whether children speaking languages that have been noted as verb friendly such as Japanese and Chinese more readily learn and extend novel verbs than children speaking English, reputed to be a "noun-friendly" language. Some researchers have claimed that Chinese and Japanese are more verb-friendly languages than English, mainly because of their grammatical as well as lexical distributional properties (Choi & Gopnik, 1995; Ogura, 2001; Tardif, 1996; cf. Gentner, 1982). With argument dropping, verbs should be relatively more frequent in Chinese and Japanese than in English. Additionally, the morphological simplicity of Chinese verbs might give an advantage to Chinese verb learners, as children do not need to learn various inflectional forms of the same verbs (Tardif, 1996).

From a different theoretical perspective such as syntactic bootstrapping hypothesis, the opposite prediction can be made. The syntactic bootstrapping hypothesis asserts that children rely on the syntactic structures in which verbs appear to infer their meanings (e.g., Fisher, 1996; Gleitman, 1990; Naigles, 1990). Granting that Chinese does not have much in the way of morphology, Lee and Naigles (2008) argue that syntactic bootstrapping is possible in Mandarin Chinese because children hear verbs in multiple sentence frames and can rely on regularities in how verbs are used syntactically. For example, certain verb classes are more likely to occur with locative or prepositional phrases, and transitive verbs are reliably signaled by the use of postverbal noun phrases—when they appear. In natural discourse, however, children may not hear a new verb used in different phrasal frames at that very occasion; it is more likely that children hear a verb but in a single frame—as in the present study—at a time. Here, Chinese children may be at a serious disadvantage relative to English-reared children who can exploit the argument structure that is usually present in English for learning and extending a novel verb.

According to the syntactic bootstrapping hypothesis, which emphasizes the role of argument structure for the inference of verb meaning, Chinese and Japanese children might be at an equal disadvantage for *novel* verb learning. On the other hand, if morphological information distinguishing verbs from nouns also matters, the disadvantage for Chinese children may be more serious than for Japanese children.

In the present research, to examine how the richness of morphosyntactic cues affects novel verb learning, we examined variability in argument structure both within and across languages. In English and Japanese, even when the information about argument structure was not provided, the word's form class could be inferred from the morphological information. Chinese thus presents an interesting test case for the use of argument structure and for how the absence of argument structure influences object versus action word mapping because the words without morphology are so ambiguous with respect to form class. In languages that use distinct morphology for nouns and verbs, once children learn the relation between word forms and word meanings (e.g., Golinkoff, Hirsh-Pasek, & Schweisguth, 2001), it is not possible to test whether they are more willing to map a new word to an object or to an action without being influenced by the form in which the word is presented. In Chinese, this is perfectly possible.

Within language, in English and Japanese in particular, we set up two conditions where verbs are introduced with or without arguments. In previous studies with Japanese children (Imai et al., 2005), novel verbs were presented without arguments (e.g., "Mite, X-teiru! "Look!, X-ing!"). The verb was offered in the present progressive tense, which clearly indicated that the word was a verb—at least to adults. However, children might profit from explicit specification of the arguments of the verb even when they can be inferred from contextual cues.

In summary, this research should illuminate the question of what is universal and what is language specific in young children's noun and verb learning, and how children' use of argument structure interacts with linguistic properties of the input language. Six studies were conducted across three languages.

Study 1: Japanese Children's Novel Noun and Verb Learning

Study 1 examined how monolingual 3- and 5-year-old Japanese children map a novel noun and a verb and how they extend it to a new situation, presenting a word in one of the three conditions: novel noun, bare verb, and verb with arguments. Study 1 was in part a replication of Study 1 in Imai et al. (2005), with additional specification of verb arguments. Of particular interest here is whether Japanese children still learn novel nouns more readily than novel verbs when the verbs were presented in full argument structure.

Method

Participants. Forty-one 3-year-old ($M = 3.6$, range $= 3.0 - 4.1$) and forty-two 5-year-old ($M = 5.5$, range $= 5.0 - 6.0$) monolingual, normally developing Japanese children participated in the study. Six additional 3-year-olds were tested but eliminated from the final sample for a side bias (2), for failing to complete the study (2), and for being bilingual (2). (Children were judged to be "side biased" when they selected the video on the same side, either left or right, throughout the six trials.) Within each age group, children were randomly assigned to one of the three conditions: noun, verb with arguments, and bare verb conditions. The proportion of boys and girls was approximately equal within each age group, and the age distribution (the mean age and range) was the same across the three conditions. Children lived in a suburban city in the Greater Tokyo area and were mostly from middle-class families.

Stimulus materials. Six sets of video action events that were identical to those used in Study 1 of Imai et al. (2005) served as stimulus materials. Each set consisted of a standard event and two test events, each lasting approximately 10 s. In the *standard* event, a young woman did a novel repetitive action with a novel object (e.g., a woman holds a brown plastic drainpipe in her right hand and pushes it outward with a punching motion). The two *test* events were variants of the standard event. In one, the same person did the same action, but the object was replaced with an object that was distinctively different from the standard in all perceptual dimensions, particularly in shape (action-same-object-change, henceforth AS). In the other test event, the theme object was the same but the action was distinctively different from the action in the standard event (object-same-action-change, henceforth OS). In both test videos, the actor was the same as the one in the standard picture. We made the action as perceptually stable and salient as possible to assure that young children would be able to decompose the action event into agent, action, and object components. (See Table 1 for the list of the actions and objects used in the six sets.)

Procedure. Participants were tested individually at the preschool they attended by a female native speaker. The experimental procedure was the same as that in Imai et al. (2005) except that the stimulus presentation was controlled by PowerPoint.

As in Imai et al. (2005), children received four warm-up trials to make sure that they could indicate what they thought to be the correct answer by pointing to one of the two test video clips. Care was taken so that the practice trials would not lead to any attentional bias toward the object or action in the event during the test trials. In the first two practice trials, they were shown two familiar objects (e.g., a cat vs. a dog) and were asked to identify the object the experimenter referred to "e.g., a dog." In the next two practice trials, they were shown a person doing two familiar actions. In one trial, for example, a woman was jumping in one video and clapping hands in the other, and children were asked, "Where is she jumping?" The last warm-up trial first presented an actor doing a novel action with a novel object, followed by two test events shown simultaneously and side by side. One was exactly the same as the standard; the other was totally different both in the action and in the object, although the actor was the same. As in the test trials, a novel word (either a noun or a verb,

Table 1
Description of the Actions and Objects Used in Studies 1–6

	Standard	Action for the object same test	Object for the action same test
Set 1	A woman is rolling the object (a football-shaped orange Frisbee with fins) between the palms of her hands.	A woman is lightly tossing and catching the object with both hands.	A blue candleholder in the shape of a cup with a long stem.
Set 2	A woman is holding the object (a long blue plastic arch-shaped object) behind her back, pulling it up and down.	A woman is holding the object in front with both hands, twisting her torso from side to side.	A long narrow meshed black band made of rubber.
Set 3	A woman is holding the object (a brown plastic drainpipe) in her right hand and pushing it outward with a punching motion.	A woman is holding the object in her right hand and tapping it against her left shoulder.	A round metallic timer.
Set 4	A woman is holding the object (a blue rubber dog toy consisting of two large loops), both hands at chest level, twisting the object so that it bends in the middle.	A woman is holding the object in her right hand and slightly moving her hand so that the object flops up and down.	An octagon-shaped rubber Frisbee ring with blue/black stripes.
Set 5	A woman is holding the object (a green metal spherical trellis on a long, thin stem) in her right hand, pushing it out with a stabbing motion.	A woman is holding the object in her right hand and tapping it against her right knee, which she is raising at the same time as she is lowering the object.	A narrow white cylindrical plastic trellis.
Set 6	A woman is tapping the object (a donut shaped plastic toy for cats) against her thigh.	A woman is holding the object with the index fingers of each hand stuck into the hole in the center and rolling the object around her fingers.	A large gray plastic curved pipe.

depending on the condition the child was assigned to) was introduced. The child was asked to which movie the novel word applied.

After the warm-up trials, children received six test trials. The standard event was presented for 30 s during which a novel word was presented. Table 2 gives the instructions for each language. The target word was introduced approximately 2 s after the standard movie began to make sure that the word was said while the actor was doing the action. The word was repeated (in the appropriate frame for the condition) three times for each scene (see the Appendix for a list of the nonsense words).

Two test events were then offered simultaneously and side by side on the same monitor. The participant was asked to which of the two events the target word should be extended. Presentation order of the six sets was randomized, and the location of the AS and OS test events was counterbalanced across the six sets within each participant.

Conditions and instructions. Novel words were presented either as a noun or as a verb. In the *noun* condition, children heard, "Look, this is (a) X!" In Japanese, no singular–plural distinction is made. Thus, in the actual Japanese instruction, children heard, "Kore (this) wa (topic) X desu (IS)," where there is no number marking (see Imai & Haryu, 2001). Verbs were presented in two different forms: one with full arguments (*verb with arguments* condition) and the other with no arguments (*bare verb* condition). In the verb with arguments condition, the word "oneesan ('girl')" is used for the subject, and "nanika ('something')" was used to refer to the novel object ("Oneesan ga nanika o X-teiru" "The girl is X-ing something"). In the *bare verb* condition, the subject and the object were not specified in the sentence, but a novel word could be identified as a verb by the morphological affix "-teiru."

Results

The proportion of the AS responses is shown in Table 3. Children's performance in the noun and bare verb conditions replicated that in the noun and verb

Table 2

Conditions and Instructions for Studies 1–6

Language	Condition	Instruction during verb presentation	Instruction for test
English	Noun (Study 2)	"Look! This is a X!"	"Where is the X? Can you point to the X?"
	Bare verb (Study 2)	"Look! X-ing"	"Where is X-ing?"
	Verb with arguments (Studies 2, 6)	"Look! She is X-ing it"	"Where is she X-ing it?"
Japanese	Noun (Study 1)	"Mite (look)! X-ga (Nominal particle) aru (exist)" "Look! There is (a) X"	"X-ga aru (exist)-no (Nominal particle)-wa (Topic particle) docchi (which movie)?" "In which (movie) is there (a) X"
	Bare verb (Studies 1 and 6)	"Mite (look)! X-teiru (X-progressive)" "Look, X-ing"	X-teiru-no(Genetive particle)-wa (Topic particle) docchi (which movie)?" "In which (movie) is (she) X-ing?"
	Verb with arguments (Study 1)	"Mite (look)! Oneesan (girl) ga (Nominal particle) nanika (something)- wo (Accusative particle) X-teiru (X-progressive)" "Look, she is X-ing something"	"Oneesan (girl) ga (Nominal particle) nanika (something)- wo (Accusative particle) X-teiru (X-progressive) no (Genetive)-wa (Topic) docchi (which movie)?" "In which (movie) is she X-ing something?"
Chinese	Noun (Studies 3, 3A, 5)	"Ni (you) kan (look)! Nali (there) you (exist) ge[a] (classifier) X" "Look! There is (a) X"	"Na (which) zhang (the quantifier) tu (picture) li (within) you (exist) ge (classifier) X?" "In which picture is there (a) X?"
	Verb with arguments: "zai" only (Studies 3, 3A, 4)	"Ni (you) kan (look)! Ayi (girl) zai (progressive) X yi (one) ge (classifier) dongxi (thing) ne (mode marking particle)" "Look (a) girl is X-ing one thing"	"Na (which) zhang (classifier) tu (picture) li (within) ayi (aunt) zai (progressive) X yi-(one) ge (classifier) dongxi (thing)?" "In which picture is she X-ing something?"
	Verb with arguments: three sentences with different auxiliaries (Studies 4, 5)	"Ni (you) kan (look)! Ayi (girl) zai (progressive) X yi (one) ge (classifier) dongxi (thing) ne (mode marking particle)" "Look (a) girl is X-ing one thing" "Ni (you) kan (look)! Ayi (girl) zhengzai (progressive) X yi (one) ge (classifier) dongxi (thing) ne (mode marking particle)""Look (a) girl is X-ing one thing" "Ni (you) kan (look)! Ayi (girl) yizhizai (progressive) X yi (one) ge (classifier) dongxi (thing) ne (mode marking particle)""Look (a) girl is always X-ing one thing"	"Na (which) zhang (classifier) tu (picture) li (within) ayi (aunt) zai (progressive) X yi-(one) ge (classifier) dongxi (thing)?" "Ayi (aunt) zai (progressive) X yi-(one) ge (classifier) dongxi (thing) de (progressive) tu (picture) shi (is) na (which) yi-(one) ge(classifier)" "In which picture is she X-ing something?"
	Bare word (Studies 3, 3A, 5)	"Ni (you) kan (look)! X!" "Look, X!"	"Na (which) ge (classifier) tu (picture) zhi (indicate) de (Nominal particle, auxiliary word) shi (is) X? " "Which picture shows X?"

[a] Note that in the Japanese instructions, the noun (either the novel noun in the noun condition or "nanika" (something) in the verb with arguments condition) was not accompanied with a classifier, whereas in Chinese, these nouns were accompanied by the generic classifier "ge." In Japanese, the number of the object is mentioned only when it is pragmatically important in the discourse. Thus, it was very unnatural to use a classifier in this situation. In contrast, in Chinese, "yi-CL-X (noun)" phrase roughly corresponds to English "a X." In our instructions, it was more natural to say "yi (one)-ge (CL)-X" than to say the bare noun without a classifier. Also, the classifier made it clear that X was a noun in the noun condition. However, the presence of the classifier does not highlight the object in the sentence in Chinese.

conditions in Study 1 of Imai et al. (2005): Both the Japanese 3- and 5-year-olds were able to map novel nouns to the OS scene, 93% and 100%, respectively. In the bare verb condition, 5-year-olds selected the AS response significantly above chance (77.4%), $t(13) = 2.43$, $p < .05$, two-tailed, but 3-year-olds were at chance level (38.1%), $t(13) = -1.072$, $p > .05$. In the verb with arguments condition, both 3-year-olds (39.3%) and 5-year-olds (69%) were at chance levels, $t(12) = -0.90$ and $t(13) = 1.56$, both $ps > .05$, respectively.

To examine whether the pattern of the results of the group analysis holds for the distribution of individuals, we counted the number of the children who selected the AS test four or more times as AS choosers (see Table 4). The results of the individual analysis converged with the group analysis; the number of AS choosers was significantly below chance by the binomial criterion in the noun condition for both ages, $p < .01$. For the 3-year-olds, the number of the AS choosers did not exceed chance either in the bare verb or in the verb with arguments condition. For the 5-year-olds, it exceeded chance in the bare verb condition in 5-year-olds, $p < .05$, but not in the verb with arguments condition, $p > .1$. In this and the following studies (Studies 2–6), the proportion of the AS choosers with the results of the binomial tests against chance is reported in Table 4.

A 2 (age) × 3 (condition) analysis of variance (ANOVA) was conducted on the proportion of the AS responses to examine the contribution of the two factors of age and the syntactic frame in which the novel word was presented (condition). A main effect for age, $F(1, 77) = 6.79$, $p < .05$, and condition, $F(2, 77) = 19.27$, $p < .01$ emerged, but the main effects were qualified by a significant Age × Condition interaction, $F(2, 77) = 3.16$, $p < .05$. To decompose the interaction, three separate 2 (age) × 2 (condition) ANOVAs were conducted. The Age × Condition interaction emerged in the analysis directly contrasting the noun and bare verb condition, $F(1, 51) = 8.02$, $p < .01$, as well as that contrasting the noun and verb with argument condition, $F(1, 51) = 4.37$, $p < .05$, but not in the one contrasting bare verb and verb with arguments conditions, $p > .05$. In the last analysis, the main effect of condition was not significant, either, $p > .05$.

Discussion

Replicating the results of Imai et al. (2005), both 3- and 5-year-old Japanese children mapped a novel noun to a novel object in an event and applied the word to the scene in which the same object appeared in a different action. Another way in which this

[a] If the number is smaller than .5 and has * or **, the object-same response was significantly above chance.
[b] The numerator represents the number of the action-same choosers; the denominator is the *n* in the condition.
$^{*}p < .05$. $^{**}p < .01$.

research replicated and extended the previous results was in demonstrating that 3-year-olds could not map and extend novel verbs to the same action in the face of an object change, whether the verb was presented with or without the specification of the arguments. It was somewhat unexpected that Japanese 5-year-olds failed to extend a novel verb to the same action scene reliably above chance when the verb was presented with the arguments but succeeded when the verb was presented without the arguments. Given that the difference between the two verb conditions (verb with arguments and bare verb) did not reach the level of statistical significance, we could not confidently conclude that Japanese children learn verbs better when unnecessary arguments are dropped. However, what is clear is that Japanese children did not gain from the specification of argument structure *when the arguments could be easily inferred from the context*. The action events used in our research involved only three elements: an actor, an action, and an object. From the Japanese point of view, it was obvious that the subject was the actor and the theme object was the novel object; hence, it was more natural that the arguments be dropped. Japanese children, in fact, could have been distracted by hearing this unnecessary information.

In Study 2, we test English-speaking 3- and 5-year-olds in the same three conditions (noun, bare verb, and verb with arguments) to compare their performance. Even though English has been characterized as a noun-friendly language, it is possible that English-speaking children learn verbs more readily than, or as readily as, Japanese children, as English offers an important structural cue to novel verb meaning, namely, argument structure. Furthermore, English-speaking children should learn and extend novel verbs more readily when the verb is presented with the arguments but not when it is presented in the bare form, as the former is much more "natural" than the latter for English speakers.

Study 2: English-Speaking Children's Novel Noun and Verb Learning

Method

Participants. Fifty-four 3-year-old ($M = 3.5$, range = 3.0–3.11) and fifty-nine 5-year-old ($M = 5.2$, range = 4.5–5.11) monolingual, normally developing English-speaking children in the suburban Greater Philadelphia area, mostly Caucasian from middle-class to upper-middle-class families, participated. An additional 21 children were tested but were not included for experimenter error (5), parental interference (4), bilingual knowledge (3), and failure to cooperate (9). The children were tested individually by a native speaker of English in two Northeastern University laboratories and were randomly assigned to the three conditions: noun, bare verb, and verb with arguments. Gender distribution and age distribution (the mean age and the age range) were approximately equal within each age/condition group.

Stimuli and procedure. The stimuli and the procedure were the same as those used for the Japanese children in

Study 1. In the noun condition, a novel word was presented as a noun ("Look, this is a X!"). In the bare verb condition, novel verbs were presented with a present progressive /ing/ ending, but the subject and the object of the sentence were dropped ("Look, X-ing!"). In the verb with arguments condition, the pronoun "she" served as the subject and "it" as the object of the sentence (e.g., "Look, she is X-ing it"). For the test, the experimenter asked the children "Where is the X?" "Where is X-ing?" "Where is she X-ing it?," respectively.

Results and Discussion

Table 3 shows the mean proportions of the AS responses by 3- and 5-year-old *English-speaking* children in all three conditions. Both the 3- and the 5-year-olds in the noun condition successfully mapped novel nouns to novel objects, reliably selecting the OS event, 85.9%, $t(17) = 9.88$, $p < .001$, for the 3-year-olds, and 89.8%, $t(19) = 14.5$, $p < .001$, for the 5-year-olds. In extending novel verbs, the 5-year-olds in the verb with arguments condition successfully selected AS events 70.1% of the time, $t(20) = 2.8$, $p < .02$. However, the 5-year-olds in the bare verb condition performed at chance, 55.6%, $t(17) = .56$, $p > .1$. The performance of the 3-year-olds did not differ from chance, whether they were in the verb with arguments condition or in the bare verb condition, 42.3%, $t(18) = 1.18$, $p > .1$ and 48.5%, $t(16) = .35$, $p > .1$, respectively. Individual analyses were also conducted, and the results converged with those of the group analysis (see Table 4).

We then examined whether English-speaking children's AS responding differed across the three conditions, and whether the effect interacted with age. The effect of condition was significant, $F(2, 107) = 23.13$, $p < .001$, as well as the Age × Condition interaction, $F(2, 95) = 3.83$, $p < .05$. As in Study 1, we conducted three 2 (age) × 2 (condition) ANOVAs to directly examine the source of the significant Age × Condition interaction. In the ANOVA contrasting the two verb conditions, the Age × Condition interaction was significant, $F(1, 71) = 4.01$, $p < .05$. In the analysis contrasting the noun and the verb with arguments condition, the interaction was also highly significant, $F(1, 71) = 7.34$, $p < .01$. However, in the analysis contrasting the noun and the bare verb condition, the Age × Condition interaction effect did not reach the level of significance.

Thus, the results of ANOVA analyses were consistent with the overall pattern suggested by the means for each age and condition. English-speaking 3- and 5-year-olds could fast-map a novel noun to an object, just as the Japanese children did in Study 1. In contrast, 3-year-old English-speaking children were not willing to extend a novel verb to an event in which the same action was performed with a different object, paralleling the findings with the Japanese 3-year-olds. The English-speaking 5-year-olds could extend a novel verb properly but only when verbs were presented with the full argument structure and not when they were presented in the bare frame. In other words, 5-year-old children from both language groups would extend a novel verb only when the verb was presented in the structural form that was most typical in their language. These results suggest that language specificity matters for the acquisition of verbs. In learning and extending verbs, children's responses are affected by the type of verb input they hear.

Study 3: Chinese Children's Novel Noun and Verb Learning

We now consider how Chinese children, learning a language that does not differentiate between nouns and verbs through the use of inflectional morphology, perform in this task. Of particular interest is whether Chinese children are able to map and extend novel nouns as well as Japanese- and English-speaking children and whether they do so at a rate better than that achieved with novel verbs, even though they tend to hear fewer nouns in the input than English-reared children. If Chinese children do manifest the noun advantage, this will provide strong support for the view that universal cognitive factors are more prominent than language-specific factors in influencing the ease and willingness with which children learn novel words. The Chinese data will also illuminate the role of syntactic cues in novel verb learning. Chinese children are offered syntactic cues less systematically than children learning either Japanese or English, both in terms of the absence of morphological marking on verbs and the occasional absence of argument structure.

Because nouns and verbs are not morphologically distinguished, the condition equivalent to the bare verb condition in Studies 1 (Japanese) and 2 (English), in which both the subject and the object of the sentence are omitted, is not achievable; a novel word cannot be presented as a verb in its bare form. Unless embedded in argument structure, it is unclear how to assign a word to a form class (see the Discussion section). We thus did not have the bare verb condition for the Chinese group. Instead, we included a *bare word* condition, in addition to the noun and the verb with arguments condition because the bare word condition in Chinese presents an ideal case to address a different but related issue. That is, Chinese allows us to ask whether young children have a predisposition to name a novel object rather than a novel action (Gentner, 1982; Golinkoff et al., 1992; Markman, 1989). If Chinese children map the novel word to the object rather than the action, it suggests that children wish to name objects in the environment independent of the frequency of verbs in the linguistic input. On the other hand, if Chinese children map the word to the action, it suggests that the type of the concept that young children are most willing to name depends on the input language.

Method

Participants. Thirty-six 3-year-old ($M = 3.5$) and thirty-six 5-year-old ($M = 5.6$) monolingual, normally developing Mandarin Chinese–speaking children living in Beijing, China, participated. Three other 3-year-olds were tested but were not included in the analysis because they were unwilling to cooperate. The participants attended a university preschool in Beijing. Their parents were mostly from middle and upper-middle class, which is comparable to the demographic background of the Japanese and American children tested in Studies 1 and 2. The children were randomly assigned to one of the three conditions: noun, verb with arguments, bare word. Gender distribution and age distribution (the mean age and range) were approximately equal within each age/condition group. They were tested individually by two female native speakers of Mandarin Chinese in a quiet room.

Stimuli and procedure. The stimuli and the overall procedure (except for the conditions and instructions) were the same as those used for the Japanese children and English children in Studies 1 and 2.

Conditions and instructions. Chinese children were randomly assigned to one of the three conditions: noun, verb with arguments, and bare word. The instructions are given in Table 2. In the noun and the verb with arguments conditions, special care was taken so that there was no ambiguity over whether the target word was a noun or a verb, respectively. In the verb with arguments condition, an auxiliary verb "zai," which marks the imperfective aspect and is usually used in expressing an ongoing action, accompanied the verb along with the subject "ayi ("the auntie [woman older than the hearer]") and the theme object "yi- (one) ge (generic classifier) dongxi (thing)." We confirmed with several preschool teachers that 3-year-old children would easily understand this construction.

Because most Chinese words consist of two syllables, we constructed two-syllable nonsense words created from combinations of existing morphemes (see the Appendix for the list of the words). When spoken, the nonsense words were not similar to existing words.

Results

As shown in Table 3, Chinese children at both ages selected AS events significantly below chance in all three conditions, all *ps* $< .05$ (see also Table 4 for the results of the individual analysis.) The rate of AS responding did not differ across the two age groups or across the three conditions. The interaction between the two factors was not significant. The results indicated that Chinese-speaking children, both 3- and 5-year-olds, have a strong tendency to fast-map a novel word to a novel object, whether the word was presented as a noun or a verb, or as a bare word, whose grammatical form class was not revealed.

Study 3A: Chinese Adults

Given the unexpected results from Chinese children, we tested Chinese-speaking adults to see how they would perform. If the children's strong bias to map a novel word to a novel object even in the verb with arguments condition was due to some unexpected factors in the instruction, Chinese-speaking adults may also show difficulty in mapping the word to the action in this condition.

Method

Participants. Forty-two undergraduate students of Peking University, all whom were native speakers of Mandarin Chinese, were individually tested. Eighteen were tested in the bare word condition and 12 each in the noun and verb with arguments conditions.

Stimuli and procedure. The stimuli and the procedure were the same as in Study 3 except that the warm-up trials were omitted. The instructions and the novel words were the same as those used for Study 3 with preschool children.

Results

Chinese adults mapped a novel noun to a novel object (70.8%), $t(11) = 2.55$, $p < .05$ (see Table 3). In sharp contrast to the preschool age children, adults in the verb with arguments condition selected the AS test 100% of the time. Also different from the children, adult Chinese speakers in the bare word condition made AS response 73% of the time, mapping the class-ambiguous word to the action rather than to the object, $t(17) = 4.03$, $p < .01$.

Discussion of Study 3 and Study 3A

The novel word presented in the verb with arguments condition was construed as a verb by Chinese adults 100% of the time. It is also interesting that the Chinese adults preferred to interpret the word as referring to the action rather than the object when the word's form class was ambiguous in the bare word condition. With the current data, it is not clear whether this apparent action-naming bias in Chinese adults is a consequence of a genuine preference for action-naming over object-naming: Chinese adults may have thought that the verb interpretation was more likely than the noun interpretation because they could come up with a good-enough name for the object (e.g., a superordinate category name such as "tool" or "toy"), but not for the action, for example. In any case, interpreting a novel word as a verb, given our stimuli and instructions in the verb with arguments condition is a perfectly reasonable course of action for adults. Even in the absence of syntactic information for verbhood (morphology or argument structure) in the bare word condition, adults did not make an object-name interpretation. In this light, Chinese children's strong object-naming bias is striking.

Taken together, it seems that noun learning is privileged independent of the properties of the language children are learning (e.g., Gentner, 1982). These results indicate that the linguistic properties of Chinese—argument dropping and morphological simplicity—that have been said to foster verb learning (Tardif, 1996, 2006; cf. Gentner, 1982) do not necessarily lead to more readiness to map and extend novel verbs in young Chinese children when compared to English- and Japanese-speaking children.

Why did Chinese children fail to learn verbs in our task, although they have many verbs in their vocabulary? What aspects of our task made it so difficult for Chinese children to learn novel verbs? We had no concern that the sentence construction used was a problem. When we embedded familiar words in the same construction, children had no problem understanding the sentence. One possible concern is that the instruction in the full argument structure condition may not have been "natural" to Chinese children, given that Chinese is also an argument-dropping language like Japanese. We originally considered a condition in which the target verb was presented with the aspect-marking auxiliary "zai" but without the arguments, which parallels to the bare verb condition in Studies 1 and 2. However, Chinese native speakers all objected to this idea, saying that presenting a *novel* word as a *verb* only with the aspectual auxiliary without both the subject and the object dropped in this situation was too "unnatural." Dropping both arguments occurs occasionally when presenting a familiar verb. Introducing a novel word without both arguments and at the same time making clear that it was a *verb*, however, would be difficult. This is probably due to the fact that unlike Japanese, Chinese lacks verb-inherent morphology. We had run a condition in which the object of the sentence (yi-ge-dongxi "a thing") was dropped but the subject was explicitly said, with 3- and 5-year-olds (12 in each age group). Performance was virtually identical to that in the verb with arguments condition. Given this, we think it unlikely that the poor performance of the Chinese children in the verb with arguments condition could be because unnecessary arguments were provided with the verb in the instruction sentence.

One thing we did note, however, was that the phonological structure of the words may have biased children against a verb interpretation. We constructed two-syllable nonsense words because bisyllabic words are most frequent in Chinese and are neutral with respect to whether they are nouns or verbs. However, verbs denoting simple and basic motions such as "run" and "jump" tend to be monosyllabic. Perhaps, then, the use of bisyllabic words biased children against the verb interpretation.

To test this possibility, in Study 4, we replicated the verb with arguments condition using monosyllabic nonsense words. Given the extreme difference between the Chinese preschoolers and the adults in the verb with arguments condition, we also tested 6- and 8-year-olds.

Study 4: Chinese Children's Novel Verb Learning With Monosyllabic Words

Method

Participants. Twelve 3-year-old (*M* = 3.6, range = 3.1 – 3.11), twelve 5-year-old (*M* = 5.7, range = 5.2 – 5.11), fifteen 6-year-old (*M* = 6.9, range = 6.5 – 7.2), and fifteen 8-year-old (*M* = 8.8, range = 8.3 – 9.3) Chinese middle-class children who were normally developing, monolingual native speakers of Mandarin Chinese, participated. Three- and 5-year-olds were from the same preschool in Beijing as the children in Study 3 but had not participated in it; 6- and 8-year-olds were from an elementary school in Beijing. The children were tested by a native speaker of Mandarin Chinese.

Stimuli and procedure. The stimuli and the procedure were the same as that used in the verb with arguments condition in earlier studies except that the nonsense words were monosyllabic. Nonsense words were made of existing phonemes in Chinese so that they sounded like Chinese words, but a nonexisting tone for the phoneme was applied (e.g., jin2, see Appendix for a list of the words used).

Results and Discussion

As shown in Table 5, the use of monosyllabic nonsense words did not drastically change the preschoolers' performance in novel verb learning: Three-year-olds still made AS responses only 25% of the time, $t(11) = 2.63$, $p < .05$, and 5-year-olds did so 33% of the time, $t(11) = 1.17$, $p > .05$. Six-year-olds' performance still did not exceed chance level (52%), $t(11) = 0.19$, $p > .1$. At 8 years of age, Chinese children finally made AS choices significantly above chance (72%), $t(14) = 2.17$, $p < .05$. A significant age difference was found, $F(3, 50) = 3.35$, $p < .05$, and post hoc pairwise comparisons (Tukey) detected a significant difference between 3-year-olds and 8-year-olds, $p = .035$, and a marginally significant difference between 5-year-olds and 8-year-olds, $p = .095$. The results of the individual analysis (i.e., the distribution of children classified as the AS choosers) are provided in Table 6.

Study 4A: Chinese Preschoolers' Verb Learning With Monosyllabic Words Presented in Three Sentence Frames

The results from Chinese children so far indicate that they have a strong object-naming bias. This bias may contribute to making novel verb mapping and extension less readily available in Chinese relative to Japanese and English.

However, it is hard to believe that Chinese 5-year-olds, if not 3-year-olds, cannot succeed in our task. Even granted that they are biased toward object-naming, there must be conditions in which they can correctly interpret the novel word as a verb and extend it to the same action. Perhaps, even though our instructions worked with Chinese-speaking adults, Chinese children need more linguistic scaffolding. In Study 4A, we tested whether Chinese 3- and 5-year-olds were able to map and extend novel verbs to the same action when additional linguistic cues were provided.

Method

Participants. Fifteen 3-year-old ($M = 3.6$, range = 3.1–3.10) and fifteen 5-year-old ($M = 5.3$, range = 5.1–5.8) monolingual Mandarin Chinese–speaking children who had not been tested in the earlier studies participated.

Linguistic cues. In the verb with arguments condition in the main study, the novel word could be unambiguously identified as a verb by the structure of the sentence, in particular, by the word order and the presence of the aspect marker "zai." However, this linguistic cue may not have been strong enough to indicate the word was a verb, given that the form of the word could not be distinguished from a noun by morphology. We thus presented the verb in three different sentences using three different auxiliaries, namely, "zai," "zhengzai," and "yizhizai," all which mark the progressive aspect, to provide even clearer and stronger clues that the novel word was a verb (see Table 2 for full instructions).

Stimuli and procedure. The stimuli were the same as those in the main study, except for the linguistic stimuli.

Results and Discussion

As shown in Table 5, even when the novel verb was presented in three different sentence

Table 5
Proportion of Action-Same Responses in Chinese Children in Studies 4–5

		Condition			
Stimuli	Age	Full argument verb one syllable word "zai" only	Full argument verb one-syllable word three sentence frames	Bare word	Noun
Original	3-year-olds	0.25*[a] (0.33), Study 4	0.34 (0.299), Study 4A	—	—

*$p < .05$. **$p < .01$.

constructions to highlight the word's form class, Chinese 3- and 5-year-olds could not succeed. Three-year-olds still made AS choices marginally below chance (34.4%), $t(14) = -2.018$, $p = .063$, and 5-year-olds responded at chance (38.9%). Children's performance was no different from that in Study 4, in which the same monosyllabic verbs were presented in a single sentence frame. No age difference was found as well (see also Table 6 for the results of the individual analysis).

Results suggest that Chinese children as old as 5 years of age could not interpret a novel word as a verb and extend it to the same action. It appears that the lack of morphological distinction between nouns and verbs makes Chinese children map and extend novel verbs *less* rather than *more* readily. Furthermore, we suspected that the lack of morphological marking to distinguish the word's form class may lead Chinese children to rely relatively more heavily on *extralinguistic* cues.

One property of our stimuli may have given children a subtle cue that the object was the focus in the event. The standard video clips showed an actor holding an object for a moment (for about half a second) before starting the action. We shot the videos this way to make sure that children saw the object clearly. It should be stressed that the object was not unnaturally highlighted in the original stimuli, and it did not seem to affect Japanese- or English-speaking children. However, if Chinese children are particularly sensitive to extralinguistic cues because linguistic cues to form class are weaker than in Japanese or English, this first segment of the video might have lead Chinese children to think that the object was in a way "topicalized." We tested this possibility in Study 5.

Study 5: Can Chinese Preschoolers Map and Extend Novel Verbs When Actions Are Highlighted?

Would Chinese 3- and 5-year-olds map and extend novel verbs more readily when the action was highlighted by reducing the salience of the theme object? Even if we observe that the Chinese children perform better with the action-highlighted video, however, it may be because the action was made more prominent than the object. If true, children should select the action when the novel word is presented as a noun or a class-ambiguous word as well. To exclude this possibility, we also tested children in the noun and bare word conditions.

Method

Participants. Forty-six Chinese 3-year-olds ($M = 3.4$, range = 3.1–3.11) and forty-six 5-year-olds ($M = 5.4$, range = 4.9–5.11) were randomly assigned to the noun, bare word, or the verb with arguments condition. Children were normally developing, monolingual Mandarin-Chinese speakers living in Beijing. There were approximately equal numbers of boys and girls within each age and condition group, and none of them had been tested in the earlier studies.

Stimulus materials and procedure. The brief object-holding segment of the video was removed so that the object was already in motion at the start of the video. Other than this manipulation, the videos were exactly the same as those used in earlier studies. The procedure, instructions, and words used for the verb with arguments condition were identical to that in Study 4A. Thus, we presented monosyllabic nonsense words with three different aspect-marking auxiliaries in order to highlight that the word was a verb. The procedure, the instructions, and the novel words used in the noun and bare word conditions were identical to the corresponding conditions in Study 3.

Results and Discussion

Removing the object-holding segment brought about a drastic change in Chinese children's novel verb learning. In sharp contrast to the failure in the earlier studies, Chinese children's verb-learning performance was now equivalent to the level of performance by Japanese- or English-speaking children. Chinese 3-year-olds were now at the chance level, just like Japanese- and English-speaking 3-year-olds (40% AS responding). The 5-year-olds now made AS selections above chance level, just like their Japanese- and English-speaking age counterparts (88%), $t(15) = 9.934$, $p < .001$. On the individual analysis, 93% of the 5-year-olds were AS choosers, $p < .01$ (see Table 6).

Children's performance in the verb with arguments condition was compared with that in Study 4A, in which the same linguistic cues were provided but the initial object-holding section was present in the video clip. Results indicated that the children performed better with the videos in which the object-holding segment was removed than with the previous version of the video, $F(1, 57) = 11.91$, $p < .01$, and the magnitude of the gain by the video manipulation was larger for the 5-year-olds than for the 3-year-olds, as suggested by the significant Age × Video Type interaction, $F(1, 57) = 7.16$, $p < .01$.

Given that the manipulation of the videos made a dramatic difference in the performance in the verb with arguments condition, it is critical to see whether the children were influenced by this manipulation only in the verb learning context or whether their AS choices also increased in the noun and bare word conditions. In those conditions, AS choices should not predominate. Both 3- and 5-year-olds mapped the novel noun to the same-object video significantly above chance level, 67% and 73% OS responding, $t(15) = 2.44$, $p < .05$, and $t(14) = 4.58$, $p < .01$, respectively, and there was no difference across the two age groups, $F(1, 29) = .36$, $p > .1$. Thus, when children made AS selections in the verb with arguments condition, they did not do so solely because the action was made perceptually more salient than the object. However, when we compared the performance of the noun condition in this study to that in Experiment 3, there was a significant decrease in the proportion of OS responding, $F(1, 51) = 7.76$, $p < .01$, with no main effect or interaction involving age. The 3-year-olds in the bare word condition still mapped the class-ambiguous word to the object, making OS choices at test 72.2% of the time, $t(14) = 7.14$, $p < .01$, and the 5-year-olds did so 63.3% of the time, $t(14) = 1.26$, $p > .1$. The children's performance here was not different from their performance in the bare word condition with the original stimuli in Study 3, $F(1, 50) = 2.80$, $p = .1$.

When we compared the children in the bare word condition and those in the verb with arguments condition on the rate of AS responding, the children in the latter condition made AS choices much more frequently, $F(1, 57) = 56.10$, $p < .01$, but this was qualified by the Age × Condition interaction, $F(1, 57) = 20.08$, $p < .01$: The difference between the two conditions was highly significant in 5-year-olds, $F(1, 28) = 20.72$, $p < .01$, but not in 3-year-olds, $F(1, 29) = 2.34$, $p > .1$.

In summary, when the action was made salient by removing a short object-holding segment, Chinese 5-year-olds were able to map and extend novel verbs to the same action. However, this shift did not create an action-naming preference in the bare word case. Although this manipulation caused a significant decrease in the noun–object mapping, Chinese children still mapped novel nouns to the object rather than the action. These results suggest that Chinese children were affected by perceptual salience to some degree in novel verb learning as well as in noun learning but that the influence of this extralinguistic cue is much stronger for the former case.

The fact that the Chinese children performed on a par with their Japanese and English same-age peers in mapping and extending novel verbs allows us to rule out another artifact. Chinese children's prior performance in the earlier studies cannot be blamed on the fact that the task was unnatural or the instructions were inappropriate for Chinese children.

The removal of the brief object-holding segment from the original stimuli strongly helped Chinese 5-year-olds. Would this manipulation also help Japanese- and English-speaking 3-year-olds, who could not map and extend novel verbs? Study 6 used the edited videos with Japanese and English 3-year-olds, who were at chance level in Studies 1 and 2.

Study 6: Can Japanese- and English-Speaking 3-Year-Olds Map and Extend Verbs When the Actions Are Highlighted?

Method

Participants. Fourteen Japanese 3-year-olds ($M = 3.6$, range = 3.0–4.0) from monolingual families living in a suburban city in the Greater Tokyo area and 16 American 3-year-olds (M = 3.6, range = 3.0–3.11) from monolingual English-speaking families living in the Greater Philadelphia area participated. The demographic and ethnic backgrounds of the children were the same as those in Study 1 (Japan) and Study 2 (United States), although none participated in earlier studies. One Japanese child (side bias) and two American children (parental interference and failure to cooperate) were also tested but excluded from the final sample. The gender distribution was approximately equal within each language.

Stimuli and procedure. The edited stimuli from Study 5 were used. Because the Japanese children in Study 1 seemed to prefer the bare verb instruction over the verb with arguments condition, we used the same procedure, instructions, and novel words as those in the bare verb condition in Study 1. On the same logic, the American children were tested with the same procedure, instructions, and novel words as those in the verb with arguments condition in Study 2.

Results and Discussion

Japanese-speaking children. As shown in Table 3, the Japanese children performed at chance, making AS selections 52.4% of the time. Of the 14 children, 6 (39%) children were AS choosers, which was not different from chance by the binomial criterion, $p > .1$ (Table 4). The performance of these children was compared to that of the Japanese 3-year-olds in the bare verb condition in Study 1. No difference was found between the two groups.

English-speaking children. English-speaking 3-year-olds also responded at chance (53.1%). Of the 16 children, 6 children were AS choosers, $p > .1$. Children's performance was not different from that of the English-speaking 3-year-olds in the verb with arguments condition in Study 2 (42.3%).

Thus, unlike the case with Chinese 5-year-olds, the removal of the brief object-holding segment from the original stimuli did not improve Japanese or English 3-year-olds' performance in mapping and extending novel verbs. Of course, the results do *not* suggest that Japanese- or English-reared children do not use extralinguistic cues *in general*, nor that they are less sensitive to extralinguistic cues than Chinese children. With the linguistic cues available to them that signal verbhood, however, Japanese- and English-reared children did not need to notice whether a half second object-holding segment preceded the action event. We elaborate on this point in the General Discussion.

General Discussion

The present research examined whether children learn novel nouns more readily than novel verbs across different languages, and how a language's linguistic properties influence novel verb learning. This article empirically evaluated these questions using a novel word-learning paradigm across three very different languages (English, Japanese, and Chinese), the latter two of which have been purported to favor the learning of verbs in the literature (e.g., Choi & Gopnik, 1995; Ogura, 2001; Tardif, 1996, 2006).

Evidence for a Potential Universal Noun Advantage

The finding that 3-year-olds in all three languages succeeded in novel noun learning but not in novel verb learning supports the view that children universally map and extend novel nouns more readily than novel verbs (Gentner, 1982; Golinkoff et al., 1992, 1996; Imai, Haryu, Okada, Li, & Shigematus, 2006; Imai et al., 2005). In our task, it was not enough for children to form a mapping between an action and a verb. To succeed, children needed to *extend* the novel verb to another exemplar, a stringent test of verb learning. Thus, the results tell us that 3-year-old children are able to map and extend a novel noun to new instances after a single word-referent pairing (e.g., Golinkoff et al., 1992; Haryu & Imai, 2002; Imai & Haryu, 2001, 2004). However, they are not able to do so as readily for novel verbs (e.g., Golinkoff et al., 1996).

Additionally, the pattern of these results from Chinese children suggests that, given the choice, young children expect novel objects to be named over actions (Golinkoff et al., 1992; Markman, 1989). The bare word condition in Chinese offered an ideal case to examine the object-naming bias as the equivalent of a linguistic projective test: What meaning would children give to a novel word presented in the absence of syntactic support? Chinese children strongly favored an object-name interpretation for a novel word. Indeed, this result was all the more impressive given that Chinese children mapped the bare word to the object even when the object was deemphasized in the action event (Study 5), and given that Chinese adults preferred to map the bare word to the action rather than the object (Study 3A). Taken together, the fact that nouns get extended more readily than verbs and the fact that children seem to have a bias to label objects corroborate prior claims for a universal noun advantage (e.g., Bornstein & Cote, 2004; Gentner, 1982; Imai et al., 2005; Kersten & Smith, 2002).

Verb Learning: Differences Across Languages

Intriguing differences emerged across language groups in what cues children used. Although Japanese- and English-speaking 5-year-olds succeeded in the verb mapping and extension task, they did so under different linguistic conditions.

Verb learning in Japanese. Replicating the results of Imai et al. (2005), 5-year-old Japanese children reliably extended a novel verb to the same action when the verb was presented with the arguments dropped, although they did not succeed when the verb was presented with its arguments. For Japanese speakers, it is natural to drop verb arguments when they can be inferred from context. From the Japanese point of view, it was obvious that the subject was the actor and the theme object was the novel object in the bare verb condition. It is possible that Japanese children were distracted by hearing this unnecessary information. At the least, Japanese children did not appear to gain from information about argument structure in this particular context, in which the subject and the object could have been easily inferred from the video, in sharp contrast to English-speaking 5-year-olds.

Verb learning in English. English-speaking 5-year-olds successfully mapped and extended the verb to the same action only when it was accompanied by its arguments. Argument dropping does not occur nearly as often in English as in Japanese or in Chinese. By age 5, children seem to be sensitive to this fact. When the novel verb was presented in an unusual structural form, even though it was marked by the progressive /ing/, and even though the arguments of the verb could have been inferred from observation, children failed. This reliance on argument structure is consistent with research demonstrating that English-reared children exploit the argument structure surrounding verbs to infer verb meaning (Fisher, 1996; Fisher & Song, 2006; Hirsh-Pasek & Golinkoff, 1996; Naigles, 1990, 1996).

Verb learning in Chinese. There has been a common assumption in the literature that learning an argument-dropping language confers an advantage on verb learning (Choi & Gopnik, 1995; Gentner, 1982; Tardif, 1996). Indeed, previous research suggests that Chinese children have more verbs in their early lexicons than do English children, for example (Tardif, 2006).

From this point of view, Chinese and Japanese children might have been expected to perform better than English-speaking children. Furthermore, Chinese children might have exceeded Japanese children because of the morphological simplicity of Chinese verbs (Tardif, 1996). In contrast, Chinese children did not perform better than Japanese- or English-speaking children. In fact, Chinese 3- and 5-year-olds both bluntly failed to map a novel verb to a novel action. Chinese children were extremely sensitive to subtle contextual cues when learning novel verbs for action events. Unless the object was deemphasized, Chinese 5-year-olds were not able to map a novel verb to the action.

One might conclude from these data that the Chinese children relied solely on perceptual cues to assign a novel word to a form class. This, however, was not the case. Using the edited videos that downplayed the salience of the object, Chinese children in Study 5 were still able to map novel nouns onto objects. Crucially, this outcome demonstrates that children are using *multiple cues* to determine word reference. At present, we can only speculate about why Chinese children demonstrated such a strong object-naming bias and why they were so sensitive to contextual cues in our task. Indeed, the linguistic cues that Chinese-speaking adults readily detect were overridden in the face of a subtle extralinguistic cue that is a half second of an object-holding scene before the start of the action. The key linguistic property that sets Chinese apart from Japanese and English is the lack of morphological distinction between nouns and verbs. Thus, unlike the case with Japanese or English, Chinese speakers cannot determine the grammatical form class of a word by inflectional morphological markings. Of course, linguistic cues such as aspect-marking auxiliaries that accompany verbs (e.g., "zai" for progressive, "le" for perfective) are salient cues to indicate verbhood for adults but they are not inherent to the word nor are they obligatory. The present research indicated that even the presence of "zai" right before the verb may not be a strong enough cue for verbhood for young children when the following word is *novel*, even though they understand the "zai + verb" construction for familiar verbs. It is possible that other auxiliaries such as "le" signal verbhood more strongly than "zai" and might lead children to identify a novel word as a verb sooner. However, this is an empirical issue that requires future investigation.

In any event, in Chinese, even though word order provides a cue for determining the form class of each word in the sentence, it is only probabilistic: Although the basic word order is subject-verb-object, there are other word orders (object-subject-verb, subject-object-verb, and verb-object-subject) that also appear in spoken language (Li et al., 1993). Thus, to identify a word's grammatical class, Chinese speakers have to coordinate semantic and grammatical cues, both at the global (such as argument structure) and at the local (such as auxiliary verb) levels, in "a complex system of mutual constraints" (Li et al., 1993, p. 193).

Chinese also has a large number of words that can be used as both nouns and verbs. In addition, as mentioned earlier, in Chinese, the notion of "word" is much less transparent than in English and in Japanese (cf. Chao, 1968). For Chinese children, then, more sophisticated linguistic knowledge may be required to identify a verb and its argument structure than for Japanese- and English-speaking children. Perhaps because linguistic cues are less easily accessible in Chinese, extralinguistic cues might be weighted more heavily in early verb learning.

Universally Shared Cognitive Factors and Language-Specific Linguistic Factors

The crosslinguistic results suggest that universally shared cognitive factors and language-specific linguistic factors both matter for early word learning. Universal biases, such as the bias to label objects, appear to characterize early word learning given the striking similarity in the developmental pattern across the three languages. However, language-specific factors come into play as well, influencing the ease with which children can map novel verbs to novel actions and factors they rely on in this process.

The pattern of crosslinguistic data here fits nicely with the emergentist coalition model (ECM) proposed by Hollich, Hirsh-Pasek, and Golinkoff (2000; Maguire, Hirsh-Pasek, & Golinkoff, 2006). The ECM makes several predictions, each of which was confirmed by the crosslinguistic data presented here. First, given the perceptual prominence of stable objects relative to relational concepts, children should universally assume that words label objects before they label actions (verbs) or properties (adjectives; Gentner, 1982; Waxman & Booth, 2003). This pattern bears out for a number of languages (e.g., Bornstein & Cote, 2004), such as English (this research; Waxman & Markow, 1995), Spanish (Waxman, Senghas, & Benveniste, 1997), and Japanese and Chinese (this research). The fact that Chinese-speaking children assumed that a class-ambiguous word was an object name rather than an action name provides additional evidence for this prediction.

Second, because children move from a reliance on perceptual to social to linguistic cues for learning words, children's movement away from the object bias to label actions will be a function of the properties of the input language. Languages that contain only subtle linguistic cues to form class should require more linguistic knowledge. In their place, children should evince continued reliance on social cues. Because Chinese children appear to have fewer clear linguistic cues to verbhood than Japanese- or English-reared children, the ECM would predict that they rely on linguistic cues later than children learning these other languages.

All in all, our results suggest that word-to-world mapping seems to be influenced by linguistic characteristics of the input language. Further, they call for a reconsideration of the linguistic factors that have been assumed to contribute to verb meaning acquisition. Morphological simplicity, for example, may not offer the toehold into verb learning once posited. Here, however, we underscore the need for future research with more fine-grained analysis of linguistic properties that might affect verb learning. For example, even though Japanese and Chinese are both argument-dropping languages, the situations and frequencies in which argument dropping occurs may differ across the two languages, in addition to differences in the morphological marking associated with verbhood: Chinese speakers may drop arguments only when the referents have been explicitly established by prior discourse, whereas arguments may be dropped in Japanese whenever the speaker thinks that the hearer can recover the arguments from context. If this is the case, it is important to examine how these potential difference influences verb learning in Japanese and Chinese children. Future research should also examine how semantic factors such as imagability and concreteness of meanings influences verb learning (Ma, Golinkoff, Hirsh-Pasek, Macronough, & Tardiff, 2008).

Discrepancy Between Our Results and Results From Production Data and Checklists: The Demanding Nature of an Extension Task

Why did children as old as 3 fail in our task even though they comprehend and produce many verbs (e.g., Choi & Bowerman, 1991; Choi & Gopnik, 1995; Fenson et al., 1994; Golinkoff et al., 2001; Ma, Golinkoff, Song, & Hirsh-Pasek, 2008; Tardif, 1996)? Importantly, we are *not* claiming that verb learning does not occur until children are 5 years old. Early appearance of verbs in children's lexicon is universally evident. Yet, the appearance of verbs in the lexicon does not mean that children appreciate the full meanings of the verbs they use. Verb meanings develop progressively, and linguistic experience is necessary to finally obtain fully adult-like representations of verb meanings (Gallivan, 1988; Imai et al., 2005, 2006; Theakston et al., 2002).

Children's early verb meanings seem to be narrowly contoured. Children first seem to associate a novel causal action to a novel label at around 18 months of age (Casasola & Cohen, 2000). However, it is highly unlikely that 18-month-olds would be willing to extend a newly learned verb to the same action when one or both of the two objects (either the agent or the patient) are changed. Maguire et al. (2002) reported that English-speaking 18-month-olds were not willing to extend a newly learned verb to the same intransitive action when the actor was changed even after they had been trained on the verb–action association with four different agents. In fact, Maguire, Hirsh-Pasek, Golinkoff, and Brandone (2008) report that children at 30–38 months do best on extending a novel verb after viewing a single agent; they cannot extend a new verb after seeing multiple agents. The bulk of the evidence suggests that 3-year-olds are reluctant to extend a novel verb to new exemplars (e.g., Behrend, 1995; Forbes & Farrar, 1995; Imai et al., 2005; Kersten & Smith, 2002).

In summary, although children may be able to associate a novel verb with a novel action as early as 18 months, their representation of verb meanings is incomplete, as revealed by their failure to extend a newly introduced verb to a situation to which it is obviously extendable for adults. Extension is an excellent test of whether a child has truly learned a verb meaning because it requires flexibility and generative use. Thus, although 2-year-olds may say a verb, it may not be until much later that they come to possess adult-like representations of the verb (see also Imai et al., 2006). Our task required verb mapping and extension. Thus, given the task demands, children should reveal proficiency later than on checklists or from production data.

Why Is Verb Learning So Slow?

This article leaves us with an unresolved question: Why are children not willing to extend verbs, and why is verb learning so slow? We alluded to perceptual and conceptual factors: Objects are easier than actions to parse from the environment (Gentner, 1982; Gentner & Boroditsky, 2001; Maguire et al., 2006). Furthermore, although objects are temporally stable, actions are ephemeral. Object boundaries are easy to find. In contrast, the beginning and the ending of an action is not clearly marked, and the action itself often undergoes change as it proceeds. Our prior work (Imai et al., 2005; Study 4) indicates that children encode and remember objects more easily than actions. On the first day, children watched each of the six original videos for 30 s in the absence of verb labels. The next day, when children were asked to say which videos they had seen before, either the object or the action was changed. Even without language, Japanese 3-year-olds experienced more difficulty encoding and remembering novel actions than encoding and remembering novel objects. The fact that actions are less easily encoded than concrete physical entities (Gentner, 1982; Golinkoff et al., 1996; Maguire et al., 2006) may well contribute to the slowness of verb learning.

Yet, difficulty in encoding actions per se cannot be the sole reason for the slowness of full mastery of verb meanings. To extend a newly learned verb, children must learn the *semantic criteria* for generalization. An action can be done with many different objects. For example, we can throw a ball, a Frisbee, a stone, a disk, or almost anything we can lift up with our hands. Suppose that a child hears the verb "throw" while watching her father throw a ball at one time and sees her father lightly *toss* a ball at another time. At still a different time, the child sees a boy throw a Frisbee to a dog. The second scene is very similar to the first because the objects—the father and a ball—are the same. To fully learn the verb "throw," she needs to not only extend the word to the similar scene but also to an event in which the actors and objects are different. In other words, to extend a verb to other instances, children need to know that agents and objects can change as long as the action is the "same." Finding the invariants in the action across exemplars is discovering an action's "verbal essence" (Golinkoff et al., 2002). The mastery of this concept is a first step toward adult-like verb meanings and it is long in coming (Behrend, 1995; Forbes & Farrar, 1995).

We are not arguing, however, that 3-year-olds never generalize verbs when the patient object is changed. Perceptual salience as well as relative novelty between the object and the action in a given action event may well influence the ease with which children extract the invariants of the action from the whole scene. Given that there is no metric for measuring relative salience or novelty of objects and actions, we cannot conclude that our results are generalizable to any situation in which children must infer the meaning of a novel verb from observing an action event. In fact, in a different series of studies, we found that children's performance in verb generalization tasks improves when the changed patient object was perceptually similar to the original object or a familiar object (Haryu, Imai, & Okada, 2003; Imai, Haryu, & Okada, 2003; see also Kersten & Smith, 2002). Also, young children may extend a verb to a new exemplar (e.g., the same action with a new actor and/or new object), when they are trained with multiple different objects and/or with linguistic contrasts (cf. Bernal, Christophe, Waxman, Braun, & Lidz, 2005). However, the story is complicated. Children may need to have a firm representation of an action, possibly even in a specific context, before they can profit from seeing multiple, more varied exemplars (Maguire et al., 2008). At some point, however, multiple exposures must be essential for verb learning.

Coming to the insight that an action can be carried out with many different objects is only the first step for verb meaning generalization. In addition, word learners need to discover that different types of verbs employ different criteria for extension. Some verbs should be extended on the basis of sameness of manner, whereas others should be extended solely on the sameness of goals or results. Still others should be extended on the basis of the sameness of direction or trajectory of motion. Which semantic component is most likely to be packaged into verb meanings also differs across languages; therefore, children need to learn this distributional pattern (e.g., Choi & Bowerman, 1991; Talmy, 1985).

In the end, the question of whether noun learning is easier than verb learning may not prove to be the central question. The real issue is identifying the universal cognitive constraints on event interpretation and studying how these constraints and the semantic and syntactic structure of a lexical category in a particular language interact with the processes used to learn words. Given the structure of the noun (object names) lexicon, fast-mapping and extension with a single instance generally works fairly well, enabling children to build up a sizable vocabulary quickly. Given the complexity involved in the process of extracting the criteria for extension of a verb, it may be more adaptive to learn and extend verbs slowly, only after hearing the same verb used to describe similar actions with different objects across different situations.

Conclusions

This article has accumulated evidence informing three issues in language acquisition. First, it has complemented the evidence found with checklists and production data in showing that nouns are mapped and extended more readily (over verbs) across three languages with different linguistic properties. Second, because this is a crosslinguistic study employing the same paradigm, the data reveal that verb learning is a protracted process very much influenced the linguistic properties of the child's language. Finally, although perceptual, social, and linguistic cues are always available to verb learners, we have discovered that when a language offers minimal linguistic cues for identifying the form class membership of a novel word, children rely for a longer time on social cues.

Does Chronic Classroom Peer Rejection Predict the Development of Children's Classroom Participation During the Grade School Years?

Gary W. Ladd, Sarah L. Herald-Brown, and Mark Reiser
Arizona State University

A sample of 398 children was followed up from ages 5 to 12 to investigate the relation between peer group rejection and classroom participation. The participation trajectories of individuals and groups of children who were rejected for differing periods of time were examined both during and after rejection using piecewise growth curve analyses. The results showed that whereas during periods of rejection, children exhibited negative or negligible growth in participation, when nonrejected, they manifested positive growth. These findings corroborated the hypothesis that (a) peer rejection creates constraints that inhibit children's classroom participation and (b) the cessation of rejection enables children to become more active and cooperative participants in classroom activities.

Support for the premise that classroom peer relations shape children's adjustment to school has grown. Nearly 20 years ago, Parker and Asher (1987) analyzed extant evidence and concluded that low peer acceptance predicted school maladjustment, particularly during adolescence. Subsequent evidence has corroborated this conclusion and shown that poor peer relations antecede school adjustment problems at earlier stages of children's school careers (Ladd, 2005; MacDougall, Hymel, Vaillancourt, & Mercer, 2001; Perry & Weinstein, 1998).

To elucidate this linkage, investigators have examined multiple features of children's classroom peer relations (e.g., friendship, friendship quality, peer group acceptance/rejection, and peer victimization; Ladd, 2003, 2005; MacDougall et al., 2001; Parker, Rubin, Price, & DeRosier, 1995) as predictors of their school adjustment. Results indicate that classroom peer rejection—which has typically been defined as how consensually disliked (relative to how consensually liked) a child is by members of his or her peer group (see Bukowski & Hoza, 1989)—is one of the strongest predictors of children's school adjustment. For example, Vandell and Hembree (1994) found that even after controlling for friendships and family characteristics, children who were rejected by peers were prone to develop scholastic difficulties. After adjusting for the predictive contributions of friendship and peer victimization, Ladd, Kochenderfer, and Coleman (1997) found that peer group acceptance/rejection was the best relational predictor of changes in kindergartners' classroom involvement and academic progress. Furthermore, Ladd and colleagues found that classroom peer rejection predicted some indicators of school maladjustment not only as children negotiated the challenges of kindergarten (e.g., school avoidance, negative school attitudes, and poor achievement; Buhs & Ladd, 2001; Ladd, 1990; Ladd, Birch, & Buhs, 1999) but also as they progressed through the early elementary school years (Buhs, Ladd, & Herald, 2006; Ladd & Burgess, 2001).

These longitudinal findings illustrate that even during the early grade school years, classroom peer rejection antecedes multiple forms of school adjustment, including children's school attitudes, school engagement, and scholastic achievement (Ladd, 2003). Although all these linkages warrant further investigation, the predictive significance of peer rejection for children's classroom participation may be among the most important to explicate. As Finn (1993) has argued, it is possible to conceptualize classroom engagement in behavioral terms and index facets of this construct by measuring the extent and quality of children's participation in classroom activities. It has

---

This investigation was conducted as part of the Pathways Project, a larger longitudinal investigation of children's social/psychological/scholastic adjustment in school contexts that is supported by the National Institutes of Health (1 RO1MH-49223, 2-RO1MH-49223, and R01HD-045906 to Gary W. Ladd). Special appreciation is expressed to all the children and parents who made this study possible and to members of the Pathways Project for assistance with data collection. Portions of this study were reported in a master's thesis that was completed by Sarah L. Herald-Brown at Arizona State University, and the authors gratefully acknowledge committee members Becky Kochenderfer-Ladd and William Fabricius for their cogent contributions.

been hypothesized that children must cultivate two forms of classroom participation—termed cooperative and independent participation—to maximize learning and achievement (Finn, 1989, 1993; Fredricks, Blumenfeld, & Paris, 2004; Ladd, Buhs, & Seid, 2000; Wentzel, 1991). Whereas independent participation denotes children's propensity to take initiative (i.e., independently seek out and pursue classroom activities), cooperative participation refers to children's adoption of the "student role" and compliance with classroom social rules and expectations (i.e., following directions, working on assigned tasks, adhering to school and classroom rules, etc.; Buhs & Ladd, 2001; Wentzel, 1991). Evidence assembled thus far corroborates the premise that both forms of participation forecast many aspects of children's school adjustment, including their scholastic progress (see Buhs & Ladd, 2001; Buhs et al., 2006; Finn, 1989; Ladd et al., 1999).

Accordingly, the purpose of this investigation was to further elucidate the relation between classroom peer rejection and the development of independent and cooperative classroom participation during the grade school years (kindergarten to Grade 6). The framework that guided this investigation was based on theory and research on the role of rejection-related processes in the development of children's school adjustment (Buhs & Ladd, 2001; Buhs et al., 2006; Coie, 1990; Ladd, 2003). Key tenets within this perspective include the following: (a) children who become collectively disliked (i.e., rejected) by classmates are increasingly subjected to peer-imposed maltreatment, including interpersonal constraints (e.g., ignoring, avoidance, and exclusion) and abuse (i.e., ridicule, harassment, and physical harm), and (b) exposure to, and especially, *sustained* experience with these rejection processes not only restricts children's opportunities to participate in classroom activities but also discourages productive forms of classroom engagement (e.g., reduces children's motivation to seek out learning activities, interact cooperatively with classmates).

The first of these two propositions has been supported by evidence indicating that peers tend to ignore, avoid, exclude, abuse, or otherwise limit the quality and quantity of rejected children's participation within classroom and playground activities, including those designed to promote learning and scholastic competence (Asher, Rose, & Gabriel, 2001; Buhs & Ladd, 2001; Ladd, Price, & Hart, 1990). The second proposition is the more innovative and least researched of the two and is based on the assumption that exposure to rejection processes expedites maladaptation, and the longer it is sustained, the greater the toll it takes on children's adjustment (Ladd, 2003). Although not as extensive, findings pertinent to this tenet indicate that sustained rather than transient classroom peer rejection (i.e., chronic peer rejection) increases the likelihood that children will develop adjustment problems (DeRosier, Kupersmidt, & Patterson, 1994; Ladd & Burgess, 2001; Ladd & Troop-Gordon, 2003). For example, DeRosier et al. (1994) found that children who experienced longer periods of rejection exhibited more serious psychological difficulties. Burks, Dodge, and Price (1995) also found that longer periods of rejection predicted increased risk for internalizing problems, but their results were limited to boys. Similarly, Ladd and Troop-Gordon (2003) established that chronic exposure to adverse peer relationships was a more powerful risk factor than strains present in children's contemporary peer relationships.

These findings are important because they link the duration of peer rejection with the severity of children's adjustment problems. At present, however, evidence is limited in that it has more to say about how chronic rejection is related to children's psychological adjustment than about its association with classroom participation during the grade school years. Furthermore, insight into the latter linkage has been occluded by design limitations, such as the propensity to study this association concurrently or across a limited number of school years. Thus, what has been learned thus far is that relatively brief periods of chronic rejection during grade school correlate positively with indicators of school maladjustment either concurrently (cross-sectional data) or at a single subsequent time point (follow-up longitudinal evidence). Because it has been rare for investigators to study the association between chronic peer rejection and classroom participation prospectively across substantial periods of schooling, little is known about how chronically rejected children *progress* toward maladaptive outcomes. Insight into this process could be gained by determining whether increments in the duration of chronic rejection predict more extended or accelerated patterns of classroom disengagement, and whether shorter versus longer periods of chronic rejection across the grade school years orient children toward differing participation trajectories.

Pursuit of these objectives also created the opportunity to explore new questions. A further implication of the premise that variability exists in the duration of rejection experiences is that children's exposure to this kind of relational adversity is not always continuous over the course of grade school. Recognizing that there also can be discontinuity in children's rejection experiences raises the question of what happens to children's classroom participation when their exposure to peer rejection ceases. To our knowledge, no one has investigated whether children's classroom participation trajectories remain stable or change after the offset of peer rejection and, in particular, whether shifts in participation trajectories are more probable or dramatic following brief versus sustained periods of peer rejection.

To address these objectives, we conducted a prospective, longitudinal investigation that spanned the elementary school years (kindergarten to Grade 6) and pursued two specific aims that were intended to elucidate the links between continuity/discontinuity in peer group rejection and children's classroom participation trajectories. Our first aim was based on the premise that exposure to peer group rejection inhibits the growth of classroom participation because rejection-related processes not only restrict children's opportunities to participate in classroom activities but also discourage productive forms of classroom engagement (e.g., reduces children's expression of initiative and their adoption of the student role in classroom activities). To be specific, we hypothesized that longer periods of chronic rejection inhibit children's classroom participation to a greater extent than shorter periods of chronic peer rejection.

The logic of this hypothesis is consonant with theories of psychological risk and stress (Dohrenwend & Dohrenwend, 1981; Johnson, 1988), in which it has been argued that the probability of maladjustment increases as a function of the length of time children are exposed to interpersonal stressors or risk factors. Furthermore, there is a modicum of evidence that implies that chronic rejection, more than brief or transient rejection, antecedes more prolonged or serious adjustment difficulties. DeRosier et al. (1994), for example, found that children who were rejected over a 2- to 3-year period, as compared to those rejected for 1 year or less, were at heightened risk for maladjustment. Evidence also links chronic rejection with *school adjustment* problems (Ladd & Burgess, 2001). Based on these findings, it was hypothesized that although children were experiencing chronic rejection, they would exhibit lower levels of classroom participation than nonrejected children, including significantly lower levels of independent and cooperative participation. Because the specific ways that chronic rejection might inhibit children's classroom participation have not been examined, we also explored whether longer periods of rejection were associated with (a) longer periods of stability or decline in participation trajectories, (b) more rapidly decelerating growth in participation trajectories, or (c) both of these possible temporal patterns.

As a first step toward addressing these hypotheses, we examined children's peer group acceptance/rejection trajectories across the grade school years and attempted to identify distinct groups whose patterns of movement in and out of rejection differed with respect to timing (i.e., earlier, later, or repeated onsets/offsets during grade school) and chronicity or duration (i.e., shorter vs. longer periods of rejection). Previous research on rejection chronicity (DeRosier et al., 1994; Ladd & Burgess, 2001; Ladd & Troop-Gordon, 2003) led us to expect that several types of rejection trajectories (i.e., rejection subgroups) might be identified, including (a) children who were rejected during the early but not during the later years of grade school, (b) children who were rejected in later but not in early years of grade school, (c) children who cycled in and out of rejection multiple times across grade school, (d) children who were rejected throughout grade school (stably rejected), and (e) children who never were rejected throughout grade school.

As part of this same aim, we examined the question of whether changes in peer group rejection—specifically, evidence of (a) a transition away from acceptance and into rejection or (b) a transition away from rejection and into acceptance among classmates—were associated with changes in children's classroom participation trajectories. Consistent with our initial premises, it was expected that the participation trajectories of children moving into rejection would decline or worsen over time. For children moving out of rejection, it was anticipated that participation trajectories would either (a) endure or worsen over time (continuity hypothesis) or (b) improve over time (discontinuity hypothesis). The possibility of these two postrejection trajectories was considered because no one has previously investigated whether children's participation remains stable or changes following the offset of peer group rejection and because both trajectories appear credible in light of extant theory and evidence.

The continuity hypothesis was based on the proposition that peer rejection suppresses children's initiative and their inclination to adopt the student role, and once inured, these participation trajectories endure or worsen as children progress through school (Buhs & Ladd, 2001; Finn, 1989; Wentzel, 1991). In contrast, the discontinuity hypothesis was built on the tenet that chronic peer rejection's effects on classroom participation trajectories are limited largely to the period during which children are experiencing rejection or rejection-related processes. Thus, in contrast to the continuity model, it could be expected that established nonparticipation trajectories would dissipate or reverse themselves after peer rejection ceased. Support for this postulate includes evidence suggesting that the effects of adverse peer experiences are not always permanent (Kochenderfer & Ladd, 1996; Kochenderfer-Ladd & Wardrop, 2001), and the assertion that children are more resilient at recovering from peer adversity during childhood than during later periods of their development (Ladd, Buhs, & Troop, 2002).

To test hypotheses about continuity/discontinuity in children's participation trajectories, it was necessary to identify groups of children whose acceptance/rejection trajectories fit previously mentioned patterns (a) and/or (b)—that is, groups that transitioned into or out of chronic rejection at one or more points during the kindergarten to grade school years. Our goal for all such groups was to compare their participation growth rates, using piecewise growth curve analyses, both before and after they were rejected. Moreover, regardless of the timing of rejection's onset, it was hypothesized that the duration of rejection (rejection chronicity) would be inversely related to growth in participation—that is, the longer children remained rejected, the less growth they were expected to exhibit in classroom participation. Support for the continuity model would consist of findings indicating that peer rejection orients children toward an enduring, irreversible disengagement trajectory—one that is maintained or becomes further elevated even *after* children are no longer rejected by their classmates. Conversely, corroboration of the discontinuity model would include findings showing that children's participation trajectories improve after the offset of chronic rejection—that is, the data pattern would imply that the cessation of peer rejection deflects children from their preexisting disengagement trajectories.

To increase the probability that observed differences in participation trajectories were attributable to variations in chronic peer rejection, data were analyzed to examine and, if necessary, control for potential covariates that might be associated with disparities in classroom participation. Because variables such as aggressive and withdrawn behavior, ethnicity, and family socioeconomic status (SES) have been linked with children's peer rejection and school adjustment (Ladd et al., 1999), these factors were examined as covariates.

The second aim of this investigation was to determine whether variations in chronic peer rejection were differentially predictive of children's cooperative versus independent participation trajectories. Although extant theory and evidence imply that longer periods of peer rejection impede the development of classroom participation, there is no comparable conceptual or empirical basis for formulating predictions about chronic rejection's effects on specific forms of classroom participation. Therefore, investigation of this aim was guided by rationales extrapolated from other sources, including research on rejected children's peer interactions, and educational theory and practice.

It seems likely that chronic classroom rejection is a detriment to the development of children's independent participation. Researchers have established that peers respond more negatively to rejected than to nonrejected children's initiatives (Dodge, 1983; Ladd et al., 1990; Putallaz & Gottman, 1981), and contemporary educational practice creates ample opportunities for classmates to negate rejected children's initiatives. Peer-mediated learning activities (e.g., cooperative learning groups, peer collaboration, activity-based instruction) have become increasingly prevalent in American grade schools (Damon & Phelps, 1989; Furman & Gavin, 1989; Radziszewska & Rogoff, 1988; Slavin, 1983), and these methods encourage classmates to respond to each other's initiatives (e.g., suggestions, requests, plans, and other expressions of initiative). If rejected children are persistently entrenched in classroom environments where their initiatives are ignored, ridiculed, or otherwise demeaned by classmates, then they may learn to refrain from such behaviors as a means of protecting themselves from further abuse. Furthermore, longer periods of rejection might inhibit independent participation because it causes children to develop feelings and cognitions that are antithetical to self-assertion and initiative (e.g., low self-efficacy, feelings of incompetence, learned helplessness). Hence, it was expected that longer exposures to peer rejection would reduce or suppress the growth of children's independent participation.

It is also conceivable that chronic rejection restrains the development of cooperative classroom participation. It has been proposed that adverse classroom experiences not only discourage children from identifying or "bonding" with school but also serve as an impetus for certain forms of behavioral disengagement, such as detachment from and resistance to the classroom culture (Finn, 1993). Because chronic rejection represents an enduring form of classroom adversity (i.e., sustained exposure to a rejecting peer environment), it may undermine school identification and encourage children to detach from the student role and disregard or resist classroom rules and expectations. However, the effect of chronic rejection on cooperative participation may not be as strong as its impact on independent participation because the former aspect of engagement is also shaped by many other socializers, some of whose influences might be more powerful than classmate's rejecting behaviors.

For example, teachers and school personnel expend considerable effort promoting cooperative participation during the early grades because it is viewed as an essential prerequisite for learning and achievement (Blumenfeld, Hamilton, Bossert, Wessels, & Meece, 1983; Wentzel, 1991). Similarly, parents often socialize these behaviors from an early age as a means of preparing children for school. For these reasons, it was anticipated that chronic rejection would be more strongly associated with changes in children's independent participation compared to cooperative classroom participation.

Method

Participants

Participants for this study were 398 children (199 boys and 199 girls) who were recruited into a longitudinal investigation as they entered kindergarten ($M_{\text{age}} = 5.50$, $SD = 0.34$) and followed yearly until they completed sixth grade ($M_{\text{age}} = 11.7$, $SD = 0.57$). Consent was obtained from school districts before recruitment began, and written informed consent was obtained from parents prior to children's participation in the study. Of the families who were invited to join the investigation, 95% consented to their child's participation. European American children (77.5%), African American children (17.9%), Latino/Hispanic children (1.3%), and children from mixed or other ethnic/racial backgrounds (3.3%) were included in the sample. At the time of recruitment, children lived in a wide range of socioeconomic households: 36.8% were lower to middle income ($0 – $20,000), 30.6% were middle income ($21,000 – $40,000), and 32.6% were middle to high income (above $41,000).

Over the course of this investigation, participants became increasingly dispersed across classrooms and school districts. When children moved or changed schools, permission was sought from administrators, teachers, and parents to extend the project into their schools. Only those classmates who had written informed parental consent (and child assent) participated in the study. The number of teachers who participated in this study per assessment period ranged from 32 to 282, and the number of classmates who contributed data per assessment ranged from 964 to 3,030.

Measures

To the extent possible, data were gathered from multiple informants to reduce problems associated with shared method variance. Different informants provided data on children's peer rejection (i.e., classmates), classroom participation (i.e., teachers), behavior with peers (i.e., independent observers), and family SES and ethnicity (i.e., parents).

Peer rejection. A roster-and-rating sociometric technique was administered in classrooms to obtain classmate's reports of children's peer acceptance/rejection (Asher & Dodge, 1986; Asher, Singleton, Tinsley, & Hymel, 1979). Classmates (those with permission) rated each other on the following likability criterion: "How much do you like to play with this person in school?" For fourth-grade and older participants, this criterion was changed to " . . . hang out with . . .."

Prior to administering the scale, participants were taught to define the scale points as 3 = *I like to play with this person a lot*, 2 = *I like to play with this person sometimes*, and 1 = *I don't like to play with this person very much*. For children in kindergarten to Grade 2, a felt board containing classmate's pictures was used instead of a class roster, and respondents rated classmates during individual interviews by sorting their pictures into boxes marked (in text and graphics) with the same three scale points. Because the definitions of scale points were somewhat lengthy, these anchors were abbreviated on sort boxes and class rosters as "a lot," "sometimes," and "not much." The ratings children received from classmates were averaged and standardized within classrooms. It has been established that this measure yields reliable and valid data with younger and older children (Asher et al., 1979; Cillessen & Bukowski, 2000; Ladd, Herald, & Andrews, 2006).

Independent and cooperative classroom participation. Measures of these constructs were obtained during the spring of every grade by asking teachers to rate items from corresponding subscales of the Teacher Rating Scale of School Adjustment (Birch & Ladd, 1997; Ladd, Kochenderfer, & Coleman, 1996). These subscales yield reliable and valid scores with grade school children (Buhs et al., 2006; Ladd et al., 2000). Independent participation was measured with a four-item subscale (sample items: "works independently," "self-directed child"; αs ranged from .85 to .89), and cooperative participation was assessed with a seven-item subscale (sample items: "accepts responsibility for a given task," "follows teacher's directions"; αs ranged from .88 to .93). All items were rated on a 3-point scale (0 = *doesn't apply*, 1 = *applies sometimes*, 2 = *certainly applies*), and ratings were averaged within subscales to obtain a score for each child.

Aggressive and withdrawn behavior with peers. Trained observers visited classrooms several times per week during the first 10 weeks of kindergarten and used a combination point-time and scan sampling technique (Altman, 1974; Ladd & Profilet, 1996) to sample the percentage of time participants spent in aggressive and withdrawn behaviors. Children were observed during free-play periods; after moving within earshot of a target child, observers first focused on a participant (2 – 3 s) and then looked away for an equal interval (2 – 3 s) to code the child's behavior into 1 of the 17 mutually exclusive behavioral categories. These on- and off-look intervals were repeated until a total of 27 scans had been recorded. Observers then located the next target child (children were observed in a predetermined, random order) and repeated this sampling procedure and so forth, until a set of 27 scans had been collected on all participants within a classroom. Once this cycle was completed, another set of scans was undertaken until a total of 20 sets of scans (a total of 540 scans per child) were gathered. These sets of scans were spaced at nearly equal intervals across the 10-week observation period.

Four of the 17 observational categories were used in this study: aggression, arguing, onlooking, and unoccupied. Behaviors coded as aggression and arguing with peers (i.e., hostile acts and hostile talk, respectively) were averaged to form an aggression score, and behaviors coded as onlooking and unoccupied (i.e., watching others but not interacting, and alone and off-task, respectively) were averaged to create a withdrawn behavior score.

Prior to data collection, observers learned children's names and practiced with a judge until they achieved a minimum of 80% agreement on all behavioral codes. Observers were then assigned to one or more classrooms and conducted 17% – 20% of their observations on a scan-by-scan basis with a reliability judge. Kappas for the entire scheme, which were calculated between each observers and judges, exceeded .70, and percent agreement on the codes used in this study averaged 86.8% (range = 73% – 100%).

Family SES. This variable was assessed with Entwisle and Astone's (1994) socioeconomic index (SEI). Adult caregivers (living in the home) received a demographic questionnaire as children began kindergarten and were asked to list their primary occupations and also write a description of their job and the duties it entailed. Data were gathered by phone or in person for caregivers who could not provide a written response. Participant's responses were coded by trained undergraduates into distinct occupational status categories and converted to corresponding SEI scores. Twenty percent of these data were scored by independent coders, and Kappa between pairs of coders on categories (agreement vs. disagreement) met or exceeded 78%. The highest of the SEI scores obtained within the same family was utilized as the participant's SEI score. Scores ranged from 0 to 97.16, with a median of 49.14 (scores around 50 are assigned to occupations such as electronic sales personnel, administrative support positions).

Ethnicity/race. Participants' parents indicated their children's ethnicity/race on the same demographic questionnaire that was used to gather SEI data. The categories used for this purpose were (a) European American, (b) African American, (c) Latino/Hispanic, (d) Native American, (e) Asian or Pacific Islander, and (d) other (other or mixed ethnic/racial backgrounds).

Procedure

From kindergarten through Grade 6 (for 7 years), data from participants, teachers, and parents were gathered during the spring of each school year, and within each assessment occasion all measures were administered in counterbalanced order. Participants completed the sociometric measure within individual interviews during the kindergarten, first, and second grades, and within group settings (e.g., classrooms) thereafter. This alteration reflects standard practice in research on children's peer acceptance and rejection. Observers gathered data on children's behavior, and parents completed a demographic questionnaire during the fall of children's kindergarten year. Teachers completed the classroom participation measures during each year of the project. Participants received age appropriate thank you gifts (i.e., colorful pencils, folders, and gift certificates), and teachers and parents received a cash honorarium.

Results

Data Analytic Strategy and Results of Preliminary Analyses

Variable distributions, relations, and patterns of missing data were examined to determine whether these and other properties of the data set conformed to the assumptions underlying parametric statistics and data augmentation procedures. Because it was possible to satisfy these prerequisites, multiple imputation was used to replace missing values with estimated scores. Multicollinearity and construct independence were evaluated by examining relations among predictors or criteria. Confirmatory factor analyses (CFAs) were used to evaluate dimensionality and factorial invariance of the participation measures.

The hypothesized differences in participation trajectories for individuals and groups of chronically rejected and nonrejected children were examined using piecewise growth curve analyses.

Estimation of Missing Data via Multiple Imputation

Attrition was minor with over 95% of the sample participating from kindergarten to Grade 6. Constraints on data collection (e.g., absences, moves, dropouts) caused 3.1% of the longitudinal data points to be missing (range by variable = 0.00% – 14.1%).

Missing data were estimated via NORM (Schafer, 1999), a multiple imputation program in which missing multivariate data are simulated $m > 1$ times. Three imputations were generated because for data sets containing 10% or fewer missing data points, it has been established that $n = 3$ imputations yield sufficient estimation efficiency (i.e., 97%; Rubin, 1987; Schafer, 1999). Mplus statistical software was used to estimate each of the hypothesized models from the multiple imputed data sets and to combine parameter estimates and standard errors across imputed data sets (Muthén & Muthén, 1998 – 2004).

Psychometric Properties and Factorial Invariance of the Participation Criteria

The items within the independent and cooperative participation subscales yielded scores that had no serious floor or ceiling effects and thus were retained as indicators of their designated subscales. Separate CFAs were performed for the independent and cooperative participation criteria to examine the factor structure and invariance of each measure over time. Each CFA examined the fit of a tau-equivalent model that contained seven latent participation variables—one per grade level (grade was the grouping variable)—each of which was constructed from the same set of indicators (i.e., the items administered for the subscale at each time of assessment). This model fit the data adequately for independent participation (comparative fit index [CFI] = 0.97, root mean square error of approximation [RMSEA] = 0.05, standardized root mean square residual [SRMR] = 0.05) and for cooperative participation (CFI = 0.94, RMSEA = 0.05, SRMR = 0.05), supporting the assumption that each measure tapped a single factor that was invariant (i.e., equivalent lambdas and error variances) across the seven times of assessment. Scores for independent and cooperative participation were created by averaging the ratings obtained for each subscale's items at each time of measurement (see the Method section for subscale alphas).

Relations Among Predictors and Criteria

Predictors were correlated by time of measurement, as were criteria. Multicollinearity among predictors (i.e., sex, SEI, ethnicity, aggression, and withdrawal) was not evident because the coefficients obtained were low to moderate in magnitude (*r*s ranged from −.32 to .44). In contrast, the participation criteria correlated positively and substantially across kindergarten through Grade 6 (*r*s ranged from .58 to .73). Hence, two CFAs were conducted to determine whether the independent and cooperative participation measures were sufficiently distinct to be evaluated as separate criteria. The first CFA evaluated the fit of a model in which items from both the independent and the cooperative participation measures served as indicators of a single latent variable at each time of measurement. The second CFA examined a two-variable model in which items served as indicators of their respective participation constructs at each time of assessment. Results showed that the single-latent-variable model, $\chi^2(36) = 333.72$, $p < .001$; Akaike information criterion (AIC) = 6,415.19, Bayesian information criterion (BIC) = 6,533.79, fit the data less well than did the two-latent-variable model, $\chi^2(26) = 113.98$, $p < .001$; AIC = 5,634.05, BIC = 5,748.69, and an examination of these information criterion indicated that the latter model fit the data significantly better than did the former one (i.e., smaller AIC and BIC values indicate better fit). Because these findings implied that different information was contained in the two participation measures, both were utilized in subsequent analyses.

Identifying Groups of Children With Distinct Kindergarten to Grade 6 Peer Rejection Histories

A series of analytic steps were taken to identify and describe groups of children whose rejection trajectories (i.e., patterns of movement in and out of rejection) across the kindergarten to Grade 6 school years were distinct with respect to timing (i.e., earlier, later, or repeated onsets/offsets during grade school) and chronicity (i.e., shorter vs. longer periods of rejection). First, for each participant in the sample, we determined which grades (if any) during the 7-year interval from kindergarten to Grade 6 that she or he received an averaged peer acceptance/rejection rating (from classmates) that was indicative of peer group rejection. Within each grade level, participants were designated as "rejected" if their average likability rating from classmates was more than two thirds of 1 *SD* below the mean likability rating for their classroom (i.e., their standardized peer rating score was <-0.70 *SD*; see Measures section). Averaged peer ratings rather than negative peer nominations were used for this purpose because low scores on this criterion provide a comparable marker of peer group rejection (Asher & Dodge, 1986) and because ratings possess superior psychometric properties (e.g., greater variability, normally distributed rather than skewed scores) and, thus, provided a more reliable index and consistent criterion for distinguishing rejected from nonrejected children across multiple occasions and classrooms. Although investigators sometimes use cutoffs of -1 *SD* to define rejection, reliance on less conservative criteria (e.g., $-.50$) is not uncommon. Because the former criterion identifies fairly extreme cases and would not identify children whose scores varied slightly from year to year, a moderately conservative criterion of $-.70$ was utilized (cf. Ladd & Troop-Gordon, 2003).

Second, we examined the number and sequence of grade levels across the kindergarten to Grade 6 school years that each participant met the criterion for peer group rejection, and on the basis of this information, each child in the sample was assigned to one of the following six mutually exclusive groups: (a) early chronic rejected (ECR) group (i.e., children rejected in three or four grades during the kindergarten to Grade 3 school years, but no more than one grade thereafter; $n = 45$); (b) later chronic rejected (LCR) group (i.e., children rejected in two or three grades during the Grades 3–6 school years, but no more than one grade prior to this; $n = 33$); (c) 1-year rejected (1-YR) group (i.e., children rejected in only one grade during the kindergarten to Grade 6 school years; $n = 56$); (d) sporadically rejected (SR) group (i.e., children who, from one grade level to the next, cycled in and out of rejection two or more times across the kindergarten to Grade 6 school years; $n = 17$); (e) stable chronic rejected (SCR) group (i.e., children rejected in five or more grades across the kindergarten to Grade 6 school years; $n = 51$); and (f) never rejected (NR) group (i.e., children who were never rejected across the kindergarten to Grade 6 school years; $n = 178$).

The validity of these a priori rejection groups was examined by also forming trajectory groups from participant's averaged peer acceptance/rejection ratings using growth mixture modeling (GMM; Muthén & Muthén, 1998–2004). Results showed that a four-trajectory model best fit the data (e.g., four-class model: AIC = 2,299.37, BIC = 2,342.71; three-class model: AIC = 6,067.05, BIC = 6,137.97; two-class model: AIC = 6,071.09, BIC = 6,130.20) and that these empirically derived trajectory classes included groups that exhibited (a) a declining peer acceptance trajectory (decliners), (b) an increasing peer acceptance trajectory (gainers), (c) a high-level peer acceptance trajectory (stable nonrejectees), and (d) a low-level peer acceptance trajectory (stable rejectees). Cross-tabulation of participants who were assigned to the a priori versus GMM trajectory groups indicated that except for the 1-YR and SR groups, there was substantial overlap in group membership. That is, 76% of the participants assigned to the LCR group were identified by GMM as decliners, 89% of children in the ECR group were classified as gainers, 86% of participants in the SCR group were designated stable rejectees, and 96% of participants in the NR group were identified as stable nonrejectees. Most likely, GMM did not identify trajectory classes corresponding to the 1-YR or SR groups because the participants in these a priori groups exhibited highly heterogeneous trajectories (e.g., these individuals moved in or out of rejection at different time points during the kindergarten to Grade 6 school years).

Third, analyses were undertaken to determine whether the six groups differed from each other with respect to participant's sex, race, aggressive and withdrawn behavior, and family SEI. Separate one-factor analyses of variance (ANOVAs; groups) were calculated on the three continuous variates (i.e., the behavioral and SEI scores), and z tests for proportions were computed for the two categorical variates (i.e., sex and race).

Group differences ($p < .05$) were found for sex, race, and family SEI. No significant group differences were found for either withdrawn or aggressive behavior. Sex composition differed in that whereas boys outnumbered girls by approximately 2:1 in all of the groups comprising children who were rejected more than 1 year (i.e., the ECR, LCR, SCR, and SR groups), girls outnumbered boys by approximately 2:1 in groups comprising children rejected 1 year or less (i.e., the 1-YR and NR groups). This sex difference was consistent with previous research, which has shown that more boys than girls tend to be rejected within their peer groups (Coie, Dodge, & Coppotelli, 1982; O'Neil, Welsh, Parke, Wang, & Strand, 1997). When the proportions of males within the ECR, LCR, SCR, and SR groups were compared, no significant differences were found, and the same was true for females within these groups ($z < 0.47$, *ns*). Racial composition did not differ in five of the six groups (LCR, SCR, SR, NR, and 1-YR) and averaged 79.6% European American, 16.9% African American, 1.2% Latino/Hispanic, 2.9% mixed race, and 0.2% Native American across these groups. In contrast to these groups, the ECR group contained a larger proportion of African Americans

(37.8% vs. an average of 16.9%). SEI scores, averaged by group, ranged from 35.02 to 55.68. Children in the NR group ($M = 55.57$) had higher scores than those in the ECR ($M = 40.90$) and SCR ($M = 35.02$) groups, and children in the LCR group ($M = 55.68$) had higher scores than those in the SCR group ($M = 35.02$).

Analyses of the Identified Groups' Classroom Participation Trajectories

Premises about the relation between chronic peer rejection and children's classroom participation trajectories were evaluated in a series of growth curve analyses (Mplus; Muthén & Muthén, 1998–2004). These analyses were conducted to determine whether each of the six groups' observed participation trajectories conformed to expectation. The predicted trajectory patterns were as follows. For the ECR group, it was expected that movement out of chronic rejection (rejection cessation) at Grade 3 would be accompanied by either no change in participation (i.e., trajectory continuity—continuation of the preexisting stable or downward trend) or a shift toward growth in participation (i.e., trajectory discontinuity) from Grades 3 to 6. For the LCR group, a shift from stable or positive growth to negative or declining growth in participation was expected as children transitioned into chronic rejection at Grade 3. For the SCR group, it was expected that stable chronic rejection would be associated with a sustained lack of participation (i.e., stable nonparticipation) or progressively decreasing classroom participation from kindergarten to Grade 6. For the 1-YR and SR groups, significant changes in participation trajectories were not anticipated because children's exposure(s) to peer rejection were transitive (i.e., brief or sporadic) rather than chronic. Finally, for the NR group, no significant changes in participation trajectories were expected because these children were not exposed to peer rejection during kindergarten to Grade 6.

To determine whether the data were consistent with these hypotheses, growth curve models were computed to estimate initial group differences in participation (intercept or between-group differences) and within-group growth rates in participation across kindergarten to Grade 6 (both linear and curvilinear trends). Additionally, for the two groups in which significant trajectory discontinuities were expected (i.e., the ECR and LCR groups), group-specific piecewise growth curves (Singer & Willett, 2003) also were estimated. Thus, in addition to initial status (intercepts), these group's growth rates (slopes) were estimated twice—in one case, before and after the transition from chronic rejection to acceptance (for the ECR group), and in the other case, before and after the transition from acceptance to rejection (for the LCR group). Because between-group differences were observed in sex, ethnicity, and family SES, these measures were included as covariates in all analyses.

For each analysis, unconditional models (Level 1) were initially calculated to estimate the mean trajectory for all children in the sample and to determine whether variation in individuals' trajectories (i.e., intercepts and linear slopes) relative to the mean trajectory on the targeted participation variable was sufficiently large to warrant the computation of conditional models. Quadratic and cubic trends were also tested in these unconditional models but were dropped because the variation associated with these growth parameters was statistically not significant. Conditional models (Level 2) were calculated because results for the unconditional models indicated that significant variation was present in the intercepts and/or linear slopes of individuals' trajectories ($ps > .05$). In these analyses, participation trajectories for the six groups were estimated by effects coding the categorical "groups" variable (Curran, Bauer, & Willoughby, 2004).

Independent participation. The results for this analysis are shown in Table 1 and are graphically represented in Figure 1a. Intercepts or initial status for all groups differed significantly from zero ($ts > 19.81$, $ps < .001$), and a one-factor ANOVA (groups: ECR, LCR, SCR, 1-YR, SR, and NR) performed on these means showed that although the initial (kindergarten) independent participation scores for the ECR and SCR groups did not differ significantly from each other (*ns*), both were significantly lower than those for the NR, 1-YR, SR, and LCR groups ($p < .05$). Tests on slopes indicated the following: For participants in the ECR group, the trajectory for independent participation remained flat or stable during the grades that they were rejected (kindergarten to Grade 3: −0.04, $t = -0.84$, *ns*) but increased significantly thereafter, during the grades that they were no longer rejected (Grades 4–6: 0.07, $t = 2.08$, $p < .05$). In contrast, for children in the LCR group, independent participation increased significantly across kindergarten to Grade 3 (0.05, $t = 2.35$, $p < .05$, when not rejected) but declined significantly across Grades 4–6 after they became rejected (−0.02, $t = -1.98$, $p < .05$). Participants in the SCR group had an independent participation trajectory that remained low and flat (stable) throughout grade school (−0.02, $t = -0.50$, *ns*). Equivalent slopes were found for the 1-YR, SR, and NR groups, and all were indicative of significant positive growth in independent participation from kindergarten to Grade 6 (0.03, $t = 3.83$, $p < .001$).

Cooperative participation. Results for this conditional growth model are shown in Table 1 and are

graphically depicted in Figure 1b. Intercepts or initial status for all groups differed significantly from zero (*t*s > 27.20, *p*s < .001). An ANOVA (groups: ECR, LCR, SCR, 1-YR, SR and NR) performed on children's cooperative participation scores at kindergarten showed that the differences between the ECR and SCR groups and between the LCR, 1-YR, SR, and NR groups were not significant (*ns*). Estimates of linear change showed the following: For participants in the ECR group, the trajectory for cooperative participation remained flat or stable during the grades that they were rejected (kindergarten to Grade 3: 0.03, $t = 1.08$, *ns*) but increased significantly thereafter, during the grades that they were no longer rejected (Grades 4–6: 0.04, $t = 1.97$, $p < .05$). The cooperative participation trajectory for children in the LCR group, in contrast, remained moderately high and stable during the grades that they were not rejected (kindergarten to Grade 3: 0.02, $t = 0.86$, *ns*) but descended significantly during subsequent grades when they were rejected (Grades 4–6: −0.02, $t = -1.96$, $p < .05$). Participants in the SCR group had a cooperative participation trajectory that remained low and flat (stable) throughout grade school (0.06, $t = 1.78$, *ns*). For the 1-YR, SR, and NR groups, cooperative participation remained high and stable across kindergarten to Grade 6 (0.01, $t = 0.81$, *ns*).

Discussion

The results of this investigation serve to clarify how classroom peer rejection is related to children's school engagement and, specifically, how children's movement in and out of chronic peer rejection is associated with changes in their independent and cooperative participation trajectories during the grade school years. In large part, this investigation's merits derive from the fact that its findings reflect on several fundamental but previously underresearched and untested hypotheses.

Our first aim was to evaluate the hypothesis that chronic peer rejection is a detriment to classroom engagement and, in particular, a feature of classroom social environments that inhibits children's independent and cooperative classroom participation. This hypothesis was corroborated by evidence indicating that although children were chronically rejected, they exhibited minimal or no growth in classroom participation. This relation was substantiated within each of the groups that experienced periods of chronic rejection. Slope estimates showed that children's participation trajectories were flat or declining during the periods of grade school that they were chronically rejected—specifically, the initial half of grade school for the ECR group, the latter half of grade school for the LCR group, and all the grade school for the SCR group.

It is significant that regardless of whether chronic rejection was experienced by children during the early or later years of grade school, its presence was accompanied by insubstantial growth in classroom participation. Children who were chronically rejected only during the beginning of their school careers—that is, from kindergarten to Grade 3 (i.e., the ECR

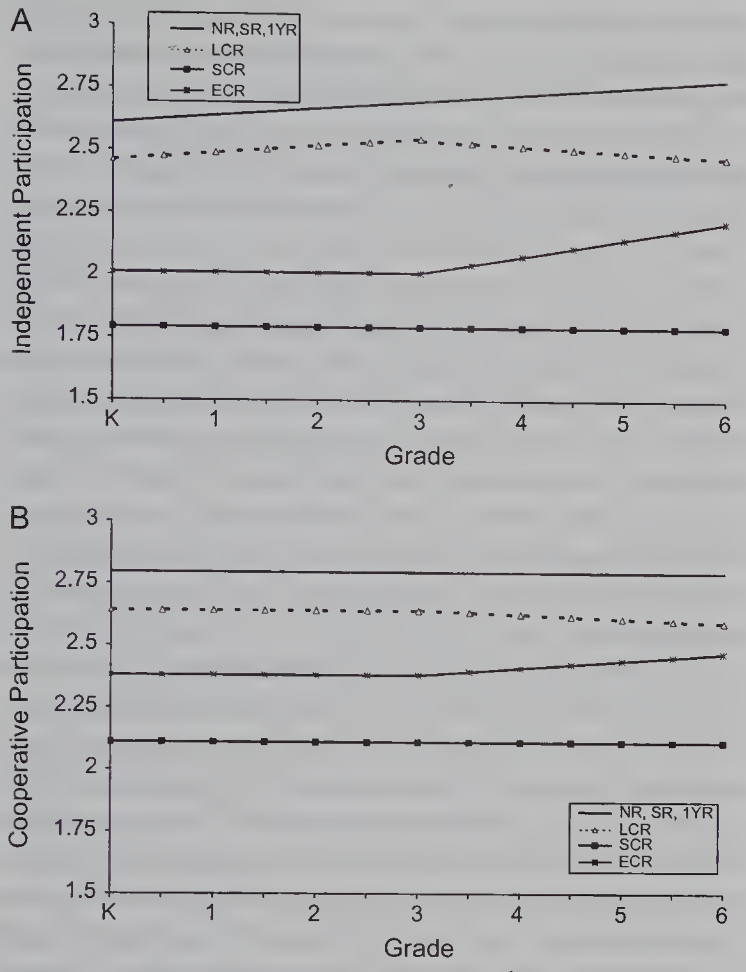

Figure 1. (a) Piecewise growth curve results for chronic rejection groups: Group-specific discontinuity model for independent participation showing differential shifts in slope when transitioning between rejection and nonrejection. (b) Piecewise growth curve results for chronic rejection groups: Group-specific discontinuity model for cooperative participation showing differential shifts in slope when transitioning between rejection and nonrejection.

group)—exhibited a significantly lower level of participation relative to nonrejected and transiently rejected children and little or no growth in participation throughout this period. This low and stable trajectory not only corroborated the premise that chronic peer rejection inhibits children's classroom participation but also was consistent with the logic that chronic rejection's effects accrue quickly and persist over time. For the children in the ECR group, chronic rejection was related to a substantial participation deficit that was evident soon after they began grade school and that persisted throughout the primary grades. Likewise, children who were not chronically rejected during kindergarten to Grade 3 but became so during Grades 4–6 (i.e., those in the LCR group) exhibited a significant downward inflection in their participation trajectories that began soon after they transitioned into chronic peer rejection. Prior to this point (i.e., during the primary grades), the participation trajectories for children in this group closely resembled those of nonrejected or transiently rejected children (i.e., children in the NR, SR, and 1-YR groups). That is, children in the LCR group exhibited significantly higher levels of participation than did children who were chronically rejected during this period (i.e., their counterparts in the ECR and SCR groups), and they showed significant positive growth in independent participation and stable levels of cooperative participation across grades kindergarten to Grade 3.

Furthermore, in all the groups that experienced chronic rather than sporadic or transient rejection (i.e., ECR, LCR, and SCR groups), the participation slopes that were estimated concurrently with chronic rejection showed that rejection was accompanied by little or no growth in *either* form of classroom participation. If rejection's role in this relation is causal (an inference that is plausible but not provable given this study's design), then these findings suggest that its "effects" on children's classroom participation were consistent with the hypothesis that chronic peer rejection is a detriment to children's independent *and* cooperative classroom participation.

Also examined as part of this first aim was the hypothesis that following a transition away from rejection and toward acceptance among classmates, children's participation trajectories would either (a) endure or worsen over time (continuity hypothesis) or (b) improve over time (discontinuity hypothesis). The evidence obtained for the ECR group provided the best test of this hypothesis because these children experienced a sustained period of peer rejection (from kindergarten to Grade 3) that was followed by a nearly equal interval of nonrejection (from Grades 4 to 6). Growth estimates for this group showed that the relatively flat participation trajectory that accompanied chronic rejection from kindergarten to Grade 3 was followed by a positive turnabout in both forms of classroom participation. That is, in contrast to the participation slopes estimated during chronic rejection (i.e., for kindergarten to Grade 3), the slopes estimated after rejection ceased (i.e., for Grades 4–6) marked the presence of significant growth in children's independent and cooperative classroom participation.

Rather than suggesting that peer rejection orients children toward enduring or irreversible participation trajectories, these findings imply that the transition from rejection toward acceptance is accompanied by an increase in classroom participation. Thus, the obtained data patterns contradicted the continuity hypothesis, which holds that peer rejection orients children toward enduring, irreversible disengagement trajectories—ones that are maintained even *after* they are no longer rejected by their classmates. Rather, the finding lent support to the discontinuity hypothesis or the view that the cessation of rejection permits growth in classroom participation and, therefore, deflects children from their preexisting participation trajectories. These findings not only corroborated the discontinuity hypothesis but also lent support to the inference that the cessation of *chronic* rejection frees children from enduring interpersonal constraints that may inhibit their classroom participation over substantial periods of time. If this inference is valid, then our data would suggest that once children are free of these constraints, they become progressively more engaged (cooperatively and independently) within classrooms.

Our data also reflected on the hypothesis that longer periods of chronic rejection inhibit classroom participation to a greater extent than shorter periods of chronic peer rejection. To corroborate this hypothesis, it would have been necessary to find that longer periods of chronic rejection (i.e., as exhibited by children in the SCR vs. those in the ECR or the LCR groups) were associated with (a) more enduring periods of stability or decline (negligible or negative growth) and/or (b) steeper rates of decline (more rapidly decelerating growth) in children's participation trajectories. As is illustrated in the following paragraphs, support was found for the former but not for the latter of these two possibilities.

Results indicated that children in the SCR group (i.e., those rejected a minimum of 5 years and a maximum of 7 years) manifested lower levels of classroom participation over a more protracted period of time compared to children in the other two chronic rejection groups (i.e., the ECR or LCR groups in which children were rejected a maximum of 2–3 years). Thus, children whose exposure to peer rejection lasted longest not only began school with low levels of both forms of participation but also exhibited no significant growth in either form of engagement throughout the entire grade school period. Moreover, this was the case regardless of the form of participation examined. That is, children in the SCR group exhibited the most sustained patterns of disengagement for both independent and cooperative participation. Essentially, children in the SCR group were relatively disengaged throughout grade school, whereas those in the other two chronic rejection groups—that is, the ECR and LCR groups—remained disengaged only as long as they continued to be rejected by their classmates. These findings further substantiate the premise that peer rejection inhibits children's classroom participation.

The evidence obtained here did not provide definitive support for the proposition that longer periods of chronic rejection produce more rapid rates of descent in children's classroom participation. Although children in the LCR group did exhibit trajectory discontinuities that were consistent with this hypothesized pattern (i.e., growth followed by significant decline in participation as children moved into chronic rejection), the participation trajectories of the other two chronic rejection groups were not characterized by change (declines) over time. Rather, stability characterized the cooperative participation trajectories of children in the ECR and SCR groups. As previously noted, for these children, chronic rejection corresponded to a substantial participation deficit that was evident during their 1st year of grade school and that was maintained as long as they continued to be rejected. It may be the case that these children's participation levels were reduced to such low levels as they began grade school that there was little room for further decline (e.g., floor effects occurred).

If it is the case that chronic peer rejection takes a negative toll on children's classroom participation, then it will be important to examine the processes that account for this relation. Potential targets for investigation include many of the intervening variables that were stipulated in the conceptual framework and hypotheses that guided this investigation. These include the many types of peer behaviors perpetrated against chronically rejected children that impede or discourage classroom participation (e.g., ignoring, exclusion, and harassment) and the plethora of rejection-induced psychological states that may produce similar consequences (e.g., fear of interacting with peers, reduced interest or motivation to participate in school activities, self-imposed isolation to escape peers' rejecting behaviors, and debilitating emotional states such as learned helplessness, anxiety, loneliness). Most, if not all, of these factors represent plausible avenues through which rejection may interfere with or reduce children's school engagement, and several have already been implicated empirically as barriers to classroom engagement, learning, and achievement (Buhs & Ladd, 2001; Fredricks, Blumenfeld, & Paris, 2004; Ladd, 1989, 2003, 2005).

Also worthy of consideration are emergent hypotheses and findings that implicate neuropsychological processes as potential mediators between interpersonal rejection and children's school performance. Rejection as an interpersonal experience has been linked with neurological activity in brain sites that are associated with pain and discomfort (Eisenberger, Lieberman, & Williams, 2003). There is also evidence to suggest that brain activity of this type impairs executive functions and thus may serve to dysregulate children's ability to focus, concentrate, and learn in school situations (Vailancourt, Clinton, McDougall, Schmidt, & Hymel, in press). Thus, it is possible that chronic peer rejection impedes children's school performance, including their ability to engage and profit from classroom activities because it dysregulates or alters brain functions that are central to learning and memory.

With respect to this investigation's second aim, the results did not provide strong support for the hypothesis that chronic peer rejection during grade school interferes with independent participation more than it does cooperative participation. Instead, the findings were more congruent with the premise that chronic rejection has similar rather than different effects on the targeted forms of classroom participation. The evidence indicated that both independent and cooperative participation changed little while children were chronically rejected, and the fact that these trajectories were fairly static raises the possibility that rejection delays rather than reduces each of these aspects of classroom engagement. The only evidence that implied that these two forms of participation develop differently was found in growth rates that were observed for nonrejected and transiently rejected children. The growth patterns for children in these groups (i.e., NR, SR, and 1-YR groups) were characterized by positive growth for independent participation and stability for cooperative participation. Furthermore, as previously noted, this same pattern typified children in the LCR group during the period of grade school when they were not chronically rejected by peers (i.e., kindergarten to Grade 3). Thus, unlike children who were chronically rejected during kindergarten to Grade 3, those who were nonrejected or transiently rejected exhibited greater growth in independent than in cooperative participation. These findings implied that there were differences in the way these two forms of participation developed but only for children who were not chronically rejected by peers. Results such as these suggest that normatively—that is, in the absence of persistent peer rejection—children tend to show stronger growth in independent participation compared to cooperative participation across the grade school period. Those who are exposed to chronic rejection, in contrast, appear to be at risk for delays or reductions in both forms of engagement.

Clearly, caution is warranted in the interpretation of these findings because even though relevant covariates were examined, other unmeasured factors (e.g., "third" variables) could have co-occurred with the documented patterns of peer group rejection. Consequently, further investigation is needed to evaluate the premises tested here, and innovative research designs and controls will be required to achieve stronger causal inferences. However, if the present findings are valid, they raise an intriguing implication: It may be possible for children to "recover" from the effects of chronic peer rejection—that is, become more engaged in classroom activities after they are no longer rejected by their classmates. These findings can be seen as a positive precedent within a body of research evidence that generally depicts few, if any, favorable outcomes for peer-rejected children.

Numerical Magnitude Representations Influence Arithmetic Learning

Julie L. Booth and Robert S. Siegler
Carnegie Mellon University

This study examined whether the quality of first graders' (mean age = 7.2 years) numerical magnitude representations is correlated with, predictive of, and causally related to their arithmetic learning. The children's pretest numerical magnitude representations were found to be correlated with their pretest arithmetic knowledge and to be predictive of their learning of answers to unfamiliar arithmetic problems. The relation to learning of unfamiliar problems remained after controlling for prior arithmetic knowledge, short-term memory for numbers, and math achievement test scores. Moreover, presenting randomly chosen children with accurate visual representations of the magnitudes of addends and sums improved their learning of the answers to the problems. Thus, representations of numerical magnitude are both correlationally and causally related to arithmetic learning.

Recent studies have revealed a consistent and robust age-related change in children's representations of numerical magnitudes. With age and experience, children progress on many tasks from relying on logarithmic representations of numerical magnitudes to relying on linear representations (Booth & Siegler, 2006; Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007; Opfer, Thompson, & DeVries, 2007; Siegler & Booth, 2004; Siegler & Opfer, 2003). The meaning of this finding is illustrated in Figure 1, which displays representative data on number line estimation. When children are presented number lines with endpoints of 0 and 100 and no marks or numbers in between and then are asked to estimate the positions of specific numbers on the number line, most kindergartners produce estimates that closely fit a logarithmic function. In contrast, most second graders generate a linear pattern of estimates; about half of first graders produce each of the two patterns. As can be seen in the figure, use of a logarithmic representation entails estimates increasing more rapidly for smaller numbers than for larger ones, whereas use of a linear representation entails estimates increasing at an equal rate throughout the numerical range.

This shift from logarithmic to linear patterns of number line estimates has been found to occur between kindergarten and second grade for 0–100 number lines and between second and fourth grades for 0–1,000 ones (Booth & Siegler, 2006; Geary et al., 2007; Laski & Siegler, 2007; Siegler & Booth, 2004). The same shift from logarithmic to linear estimation patterns occurs at the same ages on other estimation tasks, in particular, measurement estimation (drawing a line of approximately *N* units, where line lengths of 0 and 1,000 units are present as reference points) and numerosity estimation (generating approximately *N* dots on a computer screen, where 1 and 1,000 dots are the reference points; Booth & Siegler, 2006). A parallel change has been found for kindergartners', first graders', and second graders' categorization of the numbers 0–100 (Laski & Siegler, 2007).

The consistency of individual differences in performance on these tasks also attests to the effects of the changes in numerical magnitude representation. Within-grade correlations of individual second and fourth graders' degree of linearity on number line estimation, measurement estimation, and numerosity estimation tasks ranged from $r = .50$ to $r = .80$ in two experiments (Booth & Siegler, 2006). Within-grade correlations of individual kindergartners', first graders', and second graders' linearity of numerical categorization and linearity of number line estimation ranged from $r = .55$ to $r = .85$ in two other experiments (Laski & Siegler, 2007). Within-grade correlations between individual kindergartners' through fourth graders' math achievement test scores and their linearity of number line estimation have typically ranged from $r = .50$ to $r = .60$ (Booth & Siegler, 2006; Siegler & Booth, 2004).

Funding for this research was provided by the National Institutes of Health Grant HD 19011 and the Office of Educational Research and Instruction Grant R305H020060. Thanks are also due to the Hopewell Area School District for allowing us to collect data in their schools and to Mary Wolfson for assistance with data collection.

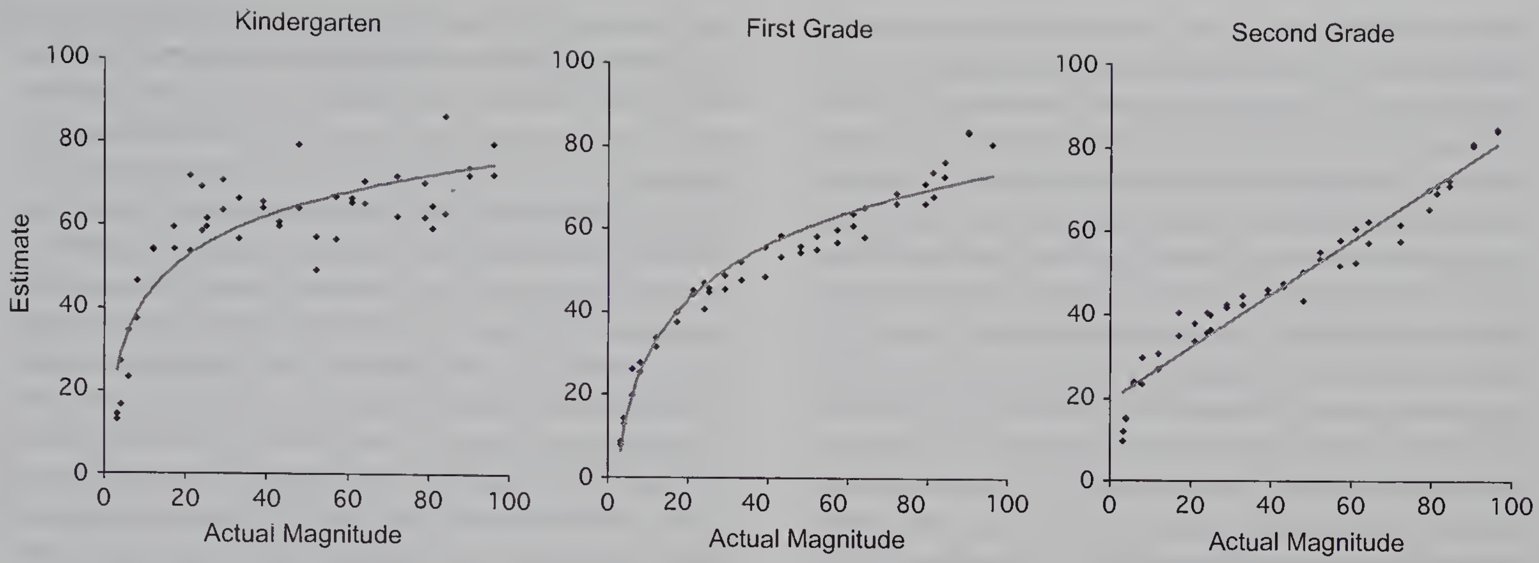

Figure 1. Median number line estimates and best-fitting function in Siegler and Booth (2004).

The central question of the present study was whether linearity of numerical magnitude representations influences acquisition of *new* numerical information. This was the first study to address this question. The particular numerical acquisition that was examined was learning answers to unfamiliar arithmetic problems. Though learning arithmetic facts has generally been viewed as a rote memorization process (e.g., Ashcraft, 1992; Campbell & Graham, 1985), we believe that such learning also includes meaningful cognitive activity. In particular, it seems to involve relying not only on verbal associations between problems and answers but also on number sense and an understanding of how quantities are combined to generate answers with particular magnitudes (see Jordan, Kaplan, Locuniak, & Ramineni, 2007, and Baroody, 1985, for similar views). Thus, there was reason to believe that children's representations of numerical magnitudes might influence their arithmetic learning.

Studies of the effects of preschool mathematics curricula provided another reason to hypothesize that numerical magnitude representations influence learning of answers to arithmetic problems. Several preschool programs, in particular, the Right Start and Number Worlds curricula (Griffin, 2004; Griffin, Case, & Siegler, 1994), are designed to inculcate a mental number line representation, akin to the linear representation of numerical magnitudes hypothesized in the present research. Griffin, Case, and their colleagues (Griffin, 2004; Griffin et al., 1994) found that having low-income preschoolers participate in a wide range of numerical activities that were intended to stimulate such a representation—numerical board games, computer games, monetary activities, number-related projects, number-related songs, and so on—improved the children's mathematical performance in first grade.

It seems likely that the extensive experience with numbers provided by Project Right Start and Number Worlds contributes to well-differentiated knowledge of a wide range of numerical magnitudes (i.e., knowledge in which students discriminate clearly among the magnitudes of large as well as small numbers rather than just among the magnitudes of small numbers). Well-differentiated knowledge of both large and small numbers seems likely to constrain the range of potential answers that receive more than minimal activation when arithmetic problems are presented. Connectionist models posit that multiple soft constraints limit potential responses to any given problem by suppressing activations of unlikely responses and boosting activation of more likely ones (e.g., McClelland, Rumelhart, & Hinton, 1986). This leads to most errors being close misses as well as to increasingly accurate performance, both of which characterize learning of arithmetic (Geary, 2006).

The implications of this analysis for arithmetic learning may be clarified by imagining a first grader being asked whether 24 + 18 might equal 82. A child who used a linear representation of the magnitudes of numbers between 0 and 100 would quickly answer "no" because the problem would elicit little if any activation of such a large answer. In contrast, for a child with a logarithmic representation of numerical magnitudes between 0 and 100, 82 would not be such an implausible answer because the logarithmic representations of 42 and 82 are not hugely different (3.74 and 4.41). Perhaps for that reason, children who generated logarithmic patterns of number line estimates were more likely to categorize 42 and 82 as being within the same numerical category than were children who generated linear estimation patterns (Laski & Siegler, 2007). Thus, linear representations of numerical magnitudes should increase the likelihood that errors on relatively large arithmetic problems will be close misses and should also increase the likelihood of retrieving correct answers.

Errors and solution time patterns on verification tasks are consistent with this analysis and with the interpretation that representations of numerical magnitudes influence arithmetic performance above and beyond knowledge of the correct answers. Both children and adults more quickly reject errors that are far from the correct sum than errors whose magnitudes are closer to the correct value (Ashcraft, Fierman, & Bartolotta, 1984; Campbell & Graham, 1985). For this and the previously described reasons, we hypothesized that the linearity of representations of numerical magnitudes would influence learning of unfamiliar arithmetic problems.

The Current Study

The present study had three main purposes. One was to examine whether first graders' representations of the magnitudes of numbers between 0 and 100 are related to their existing arithmetic knowledge and to their ability to acquire new knowledge of arithmetic problems in this numerical range. For the reasons described in the previous section, both relations seemed plausible. First graders seemed the ideal age group for testing this hypothesis because, at least within the United States, this is the grade in which there are the most substantial individual differences in representations of numerical magnitudes between 0 and 100 (Laski & Siegler, 2007; Siegler & Booth, 2004).

A second purpose of the study was to examine the relation to arithmetic learning of several other variables that seemed likely to influence such learning: overall mathematical knowledge (as indexed by scores on standardized achievement tests), prior knowledge of addition, and short-term memory for numbers. Although many studies of arithmetic knowledge have been conducted, we were unable to locate any that systematically examined relations of prior numerical knowledge to acquisition of new arithmetic knowledge under experimentally controlled conditions that guaranteed equal exposure to the problems. The present study was designed to provide information on this basic question.

In addition to being of interest in itself, examination of these predictive relations also made possible a rigorous test of the hypothesis that numerical magnitude representations influence arithmetic learning above and beyond general mathematical proficiency. If the linearity of numerical magnitude representations per se is influential, then measures of the linearity of the magnitude representations should predict learning of unfamiliar arithmetic problems above and beyond the influences of standardized math achievement test scores, prior knowledge of addition, and short-term memory for numbers.

The third major purpose of the study was to test whether provision of visual representations of numerical magnitudes exerts a causal influence on learning of answers to addition problems. External representations, including pictorial, graphic, and diagrammatic forms, are an important part of mathematics education (Seeger, 1998). They are thought to increase understanding of mathematical concepts by helping children build relations among mathematical ideas (Hiebert & Carpenter, 1992). Consistent with this claim, the National Council of Teachers of Mathematics (NCTM) recommends that teachers include multiple forms of representations when teaching mathematical concepts (NCTM, 2000). Evidence supporting this recommendation is rather weak, however. For example, Sowell (1989) concluded that the use of physical manipulatives is beneficial, but Beishuizen (1993) found that their usefulness may be limited to children with low levels of achievement. Indeed, in some contexts, provision of manipulatives appears to be harmful rather than helpful to mathematics learning (Uttal, Liu, & DeLoache, 2006). Similarly, findings from some studies suggest that provision of pictorial information is beneficial to math learning (e.g., Beishuizen, 1993; Klein, Beishuizen, & Treffers, 1998), whereas findings from others indicate that many students do not benefit from them (e.g., Cobb, 1995; Gravemeijer, 1994). Which types of external representations are most helpful and when such representations are helpful are poorly understood.

To address these issues, the first graders who participated in the present study were randomly assigned to encounter one of several types of external representations of the magnitudes of addends and sums as they attempted to learn unfamiliar addition facts. Children in the *computer generate* group were presented 0 – 100 number lines with computer-generated (correct) representations of the magnitudes of addends and sums for four unfamiliar addition problems as they tried to learn the answers to the problems. Peers in the *child generate* group were asked to estimate for themselves on 0 – 100 number lines the magnitudes of the addends and the sums as they tried to learn the answers to the four trained problems. Children in the *child and computer generate* condition first generated magnitude representations for themselves and then saw the computer-generated (correct) representations as they tried to learn the answers to the problems. Finally, classmates in the *control* group were given identical exposure to the problems and answers but were neither asked to generate a visual representation of them nor presented the accurate magnitude representations.

This design allowed us to test four main hypotheses about arithmetic learning. The first hypothesis was that linearity of numerical magnitude representations on the pretest predicts arithmetic learning. The logic underlying this prediction was that linear magnitude representations would lead children to activate a relatively narrow range of potential answers that included the correct sum rather than activating either an overly broad range of numbers that did not provide much constraint on plausible answers or a range that did not include the sum. In contrast, children who relied on a logarithmic representation of the numbers between 0 and 100 would activate a broad range of numbers in the numerical range into which answers to the four trained problems fell (sums of 27–92) because the logarithmic representation does not discriminate strongly among them. (Within a linear representation, the magnitudes of 92 and 27 differ by a ratio of 3.41:1, whereas in a logarithmic representation, the magnitudes differ by a ratio of only 1.37:1.) Depending on how the representations of the addends were implemented in the context of solving arithmetic problems, the activated range might not even include the correct answer. Consider 17 + 29, one of the problems on which children received training. The natural logs of the addends sum to 6.20, whereas the natural log of 46 is 3.83. If children use the natural log values of 17 and 29 to generate an approximate answer, the correct sum might be activated minimally if at all.

The second hypothesis was that the predictive relation between pretest linearity of numerical representations and arithmetic learning would be present above and beyond the relations to arithmetic learning of math achievement test scores, prior knowledge of other addition problems, and short-term memory for numbers. All of these other variables were expected to be related to arithmetic learning, but the relation of the linearity of each child's numerical magnitude representation to that child's arithmetic learning was expected to be present even after the other variables were considered. This prediction was a particularly rigorous test of the hypothesized relation between numerical magnitude representations and arithmetic learning because math achievement test scores share substantial common variance with the linearity of numerical magnitude representations (Booth & Siegler, 2006; Siegler & Booth, 2004). Moreover, math achievement tests have far better psychometric properties than the 5-min assessment of children's numerical magnitude representations that we used. Nonetheless, because math achievement and the other variables were hypothesized to reflect not only magnitude representations but also a variety of other influences and because magnitude representations were hypothesized to be particularly important for learning new arithmetic problems, linearity of numerical representations (as measured by linearity of number line estimates) was expected to explain variance in arithmetic learning beyond that which could be accounted for by the other three variables.

The third hypothesis was that children who were given accurate information about numerical magnitudes (those in the *computer generate* and *child and computer generate* groups) would show more learning of the correct sums, and greater improvements in the distance of their answers from the correct sum, than children in the two groups that did not receive such information. Encountering accurate visual representations of the numerical magnitudes of the addends and sum of each problem would help children align the combined magnitudes of the addends with the magnitude of the corresponding sum. It also would provide a visual processing route to the approximate value of the sum, which would support the verbal association of problem and answer.

The fourth hypothesis was that children who generated their own estimates of the magnitudes of the addends and sum (those in the *child generate* and *child and computer generate* conditions) would show greater improvement in knowledge of the trained addition problems than children who did not generate visual representations of the magnitudes of addends and sums for themselves. Asking children to generate representations of addends and sums was expected to lead to greater engagement in the task and deeper processing of the numerical magnitudes. Experimental manipulations that improve depth of processing have been found to enhance learning on a variety of mathematical and scientific problems, including addition (Calin-Jageman & Ratner, 2005), balance scales (Pine & Messer, 2000), and mathematical equality (McNeill, 2007). A similar effect was anticipated in the present context.

Method

Participants

The children who participated, 105 first graders in the second half of their academic year (57 boys and 48 girls, mean age = 7.20 years, *SD* = 0.40), were recruited from four public elementary schools in a predominately middle-income school district. The percentages of children at the schools who were eligible for free or reduced-cost lunches were 14%, 15%, 22%, and 24%, respectively. Almost all participants (96%) were Caucasian, as were both experimenters.

Children were randomly assigned to one of four conditions: *child generate* ($N = 26$), *computer generate* ($N = 25$), *child and computer generate* ($N = 27$), or *control* ($N = 27$). The slightly unequal sample sizes in the four groups were due to two children being absent when the 2-week follow-up session was conducted and one child not completing the posttest number line task due to computer malfunction. Participation was completely voluntary and no extrinsic rewards were provided.

Tasks

Number Line Estimation

Knowledge of numerical magnitudes was assessed using a computerized number line estimation task. On each problem, at the top of the screen was a number between 1 and 99 and in the middle of the screen was a horizontal number line with 0 at the left end and 100 at the right end. The experimenter explained that the number line always went from 0 to 100 and that the child should click on the line to show where he or she thought the number at the top should go. Children were first given two practice trials, which involved marking 100 and then 0 on the number line. If children did not place each practice number at the appropriate endpoint, they were shown where the number belonged. After this orienting task, the remaining numbers were presented, one at a time without feedback.

To facilitate our ability to discriminate between linear and logarithmic estimation patterns, we slightly oversampled the numbers at the low end of the 0 – 100 range by including four numbers from each decade below 30 and two numbers from each successive decade. The 26 numbers used on the number line task were 2, 3, 6, 7, 11, 14, 15, 19, 21, 23, 24, 28, 32, 36, 44, 47, 51, 58, 63, 69, 72, 76, 84, 87, 91, and 98. Children received one of three random orderings of the numbers in each session, with the orderings counterbalanced across sessions.

Math Achievement Test

The math section of the Wide Range Achievement Test – Expanded (WRAT – Expanded) was administered to obtain a measure of each child's general math knowledge. This standardized test includes questions on counting, reading numerals, measurement, spatial reasoning, and oral and written addition and subtraction. It was developed based on the curriculum content guidelines and standards developed by the NCTM (2000) and has been shown to be reliable in terms of internal consistency and stability (Robertson, 2001).

Short-Term Memory Test

Short-term memory for numbers was measured using the standard forward digit span task from the Wechsler Intelligence Scale for Children – Fourth Edition (Wechsler, 2002). The experimenter told children that she would say some numbers and that the child's job was to repeat the numbers after she stopped. Children were given one practice trial with the string "1, 2" and were corrected if they did not provide the correct response. On all trials, the presentation rate was 1 per second. The experimental task began with two trials of three digits each. If the child succeeded on at least one trial, the length of the list was increased by one digit after two presentations of that length. If the child failed on both presentations at a given level, the test was terminated. The child's score was the value of the longest series of digits correctly repeated.

Addition

Thirteen addition problems with answers between 0 and 100 were used to examine the first graders' knowledge of addition: 26 + 27, 1 + 4, 18 + 16, 38 + 39, 5 + 12, 49 + 43, 13 + 9, 48 + 17, 8 + 5, 17 + 29, 5 + 4, 46 + 35, and 9 + 18. With the exception of the few problems with very small sums, these problems were likely to be unfamiliar to first graders. All the problems with sums greater than 20 involved carrying; such problems were chosen to prevent children from solving these problems via strategies other than retrieval and thus to require them to use retrieval. A time limit of 6 s per problem was imposed for the same reason.

The instructions also conveyed the information that children should not count or use algorithms to solve the problems but rather should try to retrieve the answer. The experimenter told children that their job was to say a number that they thought could be the answer, rather than trying to add the numbers in their head, and that all of the answers would be between 0 and 100. The experimenter presented each problem verbally and asked the child to give the answer quickly. On the rare occasions when a child did not answer quickly (i.e., within 6 s after the experimenter finished reading the problem), the experimenter reminded the child not to calculate the answer, just to say a number that could be the answer if they did not know it. All children received the 13 addition problems in the same random order.

Four of the 13 addition problems were used as training items. Pilot testing indicated that these four problems were ones that the first graders rarely answered correctly on the pretest. The problems included one item that tended to elicit answers that were relatively close to the correct answer (9 + 18), two that elicited answers that tended to be incorrect by a moderate amount (26 + 27 and 17 + 29), and one that tended to elicit answers that were highly discrepant from the correct answer (49 + 43). In each session, after stating their answers for all of the problems, children in all conditions were told that they would be shown the answers to the problems and that they should try really hard to learn the correct answers. During each training session, students encountered four presentations of the first problem, followed by four presentations of the second problem, then the third, and finally the fourth. At the end of each training session, children were given a no-feedback test of the four trained addition facts, in which the experimenter presented each problem verbally and asked the child to give the answer.

Instructional Procedures

During the three training sessions, the particular procedures and types of visual information encountered by children varied with their instructional condition. Children in the *computer generate* group were shown horizontally oriented 0–100 number lines with red, blue, and purple bars that correctly represented the magnitudes of the addends and sum. Peers in the *child generate* group generated bars on number lines for themselves to estimate the magnitudes of the addends and sums; therefore, their visual representations could be accurate or inaccurate. Children in the *child and computer generate* group received both visual representations. Finally, children in the *control* group were presented the same problems and answers on the screen but without any visual representation of the numerical magnitudes. Each instructional condition is described in more detail subsequently.

Computer Generate Condition

Children were told that they would see the problem and the answer on the computer screen, that their job was to watch as the computer indicated the sizes of the numbers on the number line, and to try really hard to learn the answers to the problems. They were then given a practice problem to orient them to the important features of the task: that the red and blue bars on the computer screen represented how big the addends were and that the purple bar for the answer equaled the length of the bars for the two addends laid end to end.

The practice problem had "10 + 10" at the top of the computer screen and a line with 0 and 100 at the two ends in the middle of the screen. The experimenter went over this problem twice in somewhat different ways. First, the experimenter read the problem aloud and asked the child to repeat it. The first 10 was then highlighted in red and circled on the screen, and the child was asked to read the red number. Next, the correct magnitude for 10 was indicated in a three-step procedure: First, a small vertical hatch mark appeared on the number line; then, a red bar from 0 to the hatch mark appeared; and then, 10 was displayed above the center of the red bar. The experimenter said, "The red line shows how big 10 is. Notice that the line is red, just like the number in the problem. The first number is always going to be red." The red bar and the number above it then disappeared, and the procedure was repeated for the second 10 (which was represented with a circled blue number and a blue line). Finally, the sum, which was represented with a circled purple number and a purple bar, was presented.

At the beginning of the second time through the practice problem, the computer screen was reset to its original state. This time, the child read the first 10, which was again highlighted in red, and the screen displayed its magnitude with a red bar. The experimenter reminded the child that the red bar showed how big the first addend was. Then, the child read the second 10, and the screen displayed its magnitude with a blue bar under the number line, with the first addend and the red bar representing its magnitude remaining visible. The experimenter reminded the child that the blue bar indicated how big the second addend was and said, "Let's add the red line for 10 to the blue line for 10." At this point, the blue bar, which represented the second addend, was moved to the top of the number line, beginning where the red bar ended. Then, the purple bar that represented the magnitude of the answer appeared just under the number line, and the experimenter explained that the purple bar indicated how big 20 was and that the child should notice that the length of the red bar plus the length of the blue bar equaled the length of the purple bar. Finally, with this display remaining visible, the child was asked to read the problem one final time.

After the practice problem, children were tested on their knowledge of what the red, blue, and purple bars meant. The experimenter asked the same three questions until the child answered all of them correctly. Then, the four training problems were presented along with the correct visual representation of each one's addends and sum.

Child Generate Condition

Children in this group were given the same instructions except that they were told that they (rather than the computer) would estimate the magnitudes of the numbers on the number line. The remainder of the procedure was identical to that in the *computer generate* condition, except for the children estimating the magnitudes of the addends and sum on the number line. Red, blue, and purple bars corresponding to the child's estimates of the addends and sum for each problem (instead of the computer-generated estimates) appeared on the screen as in the *computer generate* condition.

Child and Computer Generate Condition

Children in this group were given the same initial instructions and procedure as peers in the *child generate* group. However, the second time through the problem, the screen also showed computer-generated (correct) placements on a separate number line that was positioned directly underneath the child-generated estimates for the problem. For example, for the problem 17 + 29, after the child's estimate of the magnitude of 17 appeared just above the upper number line, the computer generated the correct magnitude of 17 just above the lower number line. The experimenter then said, "This red line (pointing) is how big you thought 17 was, but *actually* this red line (pointing) is how big 17 is." Then, after the child's estimate of the magnitude of 29 appeared in blue just below the upper number line, the correct magnitude of 29 appeared in blue just below the lower number line. Next, on both number lines, the blue bar representing the magnitude of the second addend was placed at the right end of the red bar that represented the magnitude of the first addend. After that, a purple bar representing the sum of the two addends appeared below the relevant number line. On the upper number line, the purple bar corresponded to the child's estimates of the sum, whereas on the lower number line, the purple bar corresponded to the correct sum. Thus, by the end of the trial, the computer screen displayed all three of the child's estimates on the upper number line and all of the correct magnitudes on the lower line.

Control Condition

As in the other three conditions, children in the *control* group encountered each problem four times in each training session. The conditions under which children were presented each problem were also the same as in the other conditions. First, the experimenter read the addends and sum aloud. Then, the child repeated them. The next two times through the problem, the addends and sum were colored red, blue, and purple and circled as in the other conditions, and the child read them without the experimenter's help.

Procedure

Children met one-on-one with the experimenter for three 10- to 15-min sessions within a 1-week period and for a 5-min "follow-up" session 2 weeks after the third session. All sessions were conducted during the school day; children participated at a time selected by their teacher. An outline of the tasks presented in each of the four sessions is presented in Table 1.

Table 1
Measures Included in Each of the Four Experimental Sessions

Measure	Session 1 (pretest)	Session 2	Session 3 (end of training)	Session 4 (follow-up)
Number line estimation	X		X	
Math achievement test		X		
Short-term memory	X			
13-item addition test	X			X
4-item addition pretest, training, and posttest procedure	X[a]	X	X	

[a] In Session 1, the 4-item addition pretest reflected performance on the 4 items on which children subsequently received training from within the 13-item addition test.

In Session 1, children were presented the number line estimation task, the short-term memory task, and the 13-problem addition task. Then, they were presented the instructional procedure for their experimental group, followed by a no-feedback test on the four trained addition problems at the end of the session. All children received the tasks in the same order. Session 2 consisted of a pretest, training, and a posttest on the four addition training problems, followed by the math section of the WRAT. Session 3 was identical to Session 2, except that children were given the number line estimation task rather than the WRAT at the end of the session. During Session 4 (the follow-up session), children were again asked to provide sums for the same 13 addition problems as on the pretest.

No feedback regarding answers to the trained problems was given on the pretests and posttests for those problems, and only implicit feedback (i.e., the correct answer) was given during training. Children were told frequently during all parts of the experiment that they were doing well. At the end of each session, they were thanked for participating and returned to their classroom.

Results

The results are reported in two sections. In the first section, we examine for the entire sample the interrelations of performance on the four pretest tasks—addition, number line estimation, short-term memory for numbers, and math achievement test—and examine each of their predictive relation to learning of the four trained addition problems. In the second section, we examine the causal influence of computer-generated and self-generated visual representations on the learning of the trained arithmetic problems and on number line estimates. The analyses examined performance at three times: *pretest* (Session 1), *end of training* (end of Session 3), and *follow-up* (Session 4).

Predictors of Learning and Performance

Relations Among Pretest Measures

As shown in Table 2, levels of performance on all four pretest measures of numerical proficiency were positively related. The relations among number line estimation, addition, and math achievement test scores were substantial; the relations between short-term memory and the other three tasks were weaker. The correlation between linearity of number line estimates and overall math achievement test score (r = .57) was of the same magnitude as in previous studies (rs = .50 – .60).

Table 2
Correlations Among Number Line Estimation, Addition, Short-Term Memory, and Math Achievement Test Performance: Pretest Data

Measure	Number line estimation (R^2_{Lin})	Math achievement (WRAT)	Addition (PAE)
Math achievement (WRAT)	.57**		
Addition (PAE)	.41**	.48**	
Short-term memory	.07	.21*	.21*

Note. df = 103. PAE = percent absolute error; WRAT = Wide Range Achievement Test.
$*p < .05$. $**p < .01$.

Pretest Predictors of Arithmetic Learning

We examined pretest predictors of performance on the trained addition problems at the end of training and at the follow-up session for the whole sample and for each instructional condition separately. The predictive relations were similar for all conditions; therefore, only the results for the full sample are reported.

Addition knowledge. Children answered 21% of pretest items correctly. The large majority of correct answers on the pretest were on the four problems that had sums below 20—55%, versus 6% on the nine larger problems. On the four large addend problems on which children subsequently received training, they answered correctly on 7% of trials.

Knowledge of addition was also assessed through examining percent absolute error (PAE):

$$\left(\left|\frac{\text{Child's answer} - \text{correct answer}}{\text{Scale of answers}}\right|\right)$$

For example, if a child answered 80 for the problem 26 + 27, the PAE would be 0.27 ([80 – 53]/100) or 27%. PAE provides a continuous measure of the degree to which answers are of the right magnitude, which was a central issue in the present study.

Mean PAE on the pretest was 12%. Again, there was a large discrepancy between performance on the four small addend problems (PAE = 2%) and on the nine large addend ones (PAE = 17%). On the four training items, pretest PAE was 16%.

We next examined the stability of individual differences in addition knowledge, in particular, whether children's pretest addition knowledge was predictive of their posttest knowledge of the trained addition problems. To avoid the autocorrelations that would have been entailed by including the same items as predictors and predicted variables, we correlated each child's mean pretest PAE on the nine nontrained addition problems with that child's performance following training on the four trained addition problems. (Too few children answered any of these four problems correctly on the pretest for pretest number correct to be a meaningful predictor.)

PAE on the nine untrained problems on the pretest was positively related to PAE on the four trained addition problems at the end of training, $r(103) = .47$, $p < .01$, and at the follow-up, $r(101) = .62, p < .01$. PAE on the nine untrained problems on the pretest also was correlated with percent correct answers on the four trained problems both at the end of training, $r(103) = -.23, p < .05$, and at the follow-up, $r(101) = -.37, p < .01$.

We next conducted a regression analysis to determine whether pretest PAE on the nine untrained addition problems accounted for variance in learning of the four training set items beyond that which could be explained by pretest PAE on the training set items themselves. In this analysis, we first entered each child's pretest PAE on the four training set items and then their pretest PAE on the nine untrained addition problems.

As shown in Table 3, pretest PAE on the nine untrained addition problems added significant variance both at the end of training (8%) and at the follow-up (11%) beyond that which could be explained by pretest PAE on the trained problems. This finding suggests that children's general sense of the likely magnitudes of answers to addition problems predicts their subsequent learning, beyond their initial knowledge of answers to the specific problems that they are learning.

Number line estimation. To assess the relation between pretest numerical magnitude representations and addition learning, we correlated each child's R^2_{Lin} on the pretest number line estimation task with that child's percent correct answers and PAE on the trained addition facts at the end of training and at the follow-up.

R^2_{Lin} on the number line pretest predicted PAE on the trained addition facts both at the end of training, $r(103) = -.45, p < .01$, and at the follow-up, $r(101) = -.54, p < .01$. Pretest R^2_{Lin} on the number line pretest also predicted percent correct answers on the trained addition problems at the end of training, $r(103) = .23$, $p < .05$, and at the follow-up, $r(101) = .30, p < .01$. Thus, initial knowledge of numerical magnitudes predicted both learning of unfamiliar addition facts and quality of errors on them.

To determine whether pretest number line estimation was related to improvement in PAE on the addition facts, above and beyond the quality of initial answers on the problems, we conducted a regression analysis in which we first entered each child's pretest PAE on the trained addition facts and then their R^2_{Lin} values on the number line pretest. As shown in Table 3, R^2_{Lin} on the number line pretest added a substantial amount of variance to that which could be explained by pretest PAE on the trained addition

Table 3

Pretest Predictors of Improvement in PAE on Trained Addition Problems at End of Training and Follow-Up Performance

Pretest predictor(s)	% variance explained in reduction of PAE on trained problems at end of training	% variance explained in reduction of PAE on trained problems at follow-up
Trained addition problems (PAE)	31	18
Trained addition problems (PAE) + untrained addition problems (PAE)	39*	29*
Trained addition problems (PAE) + number line estimation (R^2_{Lin})	39*	29*
Trained addition problems (PAE) + WRAT score	41*	24*
Trained addition problems (PAE) + STM	33	20

Note. First row of data indicates variance in improvement in PAE on trained addition problems after training and at the follow-up that could be explained by pretest PAE on those problems. Subsequent rows indicate the variance in improvement in PAE at the end of training and at the follow-up on the trained addition problems that could be explained by considering pretest PAE on the same problems and the additional variable indicated in the left column. Thus, considering pretest number line estimation (R^2_{Lin}) as well as pretest PAE on the trained addition problems accounted for 8% more variance after training (39% vs. 31%) and 11% more variance at the follow-up (29% vs. 18%) than only considering pretest PAE on the same problems. PAE = percent absolute error; WRAT = Wide Range Achievement Test; STM = short-term memory.
*$p < .01$.

facts: 8% at the end of training and 11% at the 2-week follow-up.

Math achievement. Children's math achievement, as measured at the time of the pretest, also was predictive of their PAE on the trained addition problems both at the end of training, $r(103) = -.49, p < .01$, and at the follow-up, $r(101) = -.52$, $p < .01$. Their achievement test scores also were related to percent correct answers on the trained problems at the end of training, $r(103) = .28$, $p < .01$, and at the follow-up, $r(101) = .33$, $p < .01$. As shown in Table 3, the math achievement test scores, like pretest performance on the untrained addition problems and number line estimates, added to the variance that could be explained by pretest PAE on the trained addition facts: 10% additional variance at the end of training and 6% at the follow-up.

Short-term memory. Short-term memory for numbers was predictive of PAE on the trained addition facts both at the end of training, $r(103) = -.20, p < .05$, and at the follow-up, $r(101) = -.23, p < .05$. However, it was not related to percent correct on the trained addition problems either at the end of training, $r(103) = .11$, *ns*, or at the follow-up, $r(101) = .08$, *ns*. It also did not account for significant variance in improvement in PAE at the end of training or at the follow-up beyond that which could be explained by pretest PAE on the four trained addition problems (Table 3).

Linear representations as an independent predictor of addition learning. One of the main purposes of the study was to test the prediction that even after the effects of other aspects of numerical knowledge were considered, linearity of numerical magnitude representations would still predict arithmetic learning. Therefore, we conducted regression analyses on reduction of error on the trained addition facts by the end of training and at the follow-up. We first entered each child's pretest PAE on the trained addition facts, pretest PAE on untrained addition facts, pretest short-term memory for numbers, and math achievement test scores. Then, we entered the child's linearity of pretest number line estimates to see if it explained additional variance in the child's posttraining performance on the trained addition problems.

The linearity of pretest number line estimates added significant variance both at the end of training and at the follow-up to that which could be explained by the other variables. Pretest performance on the other four tasks explained 45% of the variance in PAE on the trained addition problems at the end of training; pretest R^2_{Lin} on the number line explained an additional 2%, $t(102) = 2.09, p < .05, d = 0.41$. The same four pretest variables explained 33% of the variance in PAE on the trained problems at the follow-up; pretest R^2_{Lin} on the number line estimation task explained an additional 6%, $t(100) = 2.88, p < .01$, $d = 0.58$. Thus, despite R^2_{Lin} on the number line task being correlated with three of the four other predictors and all of those other measures being correlated with PAE on the trained addition problems at the end of training and at the follow-up, linearity of number line estimates accounted for variance in arithmetic learning that could not be explained by the other measures of numerical knowledge.

Effects of Instructional Condition

To examine the effects on arithmetic learning of the experimental manipulations, we contrasted performance in the four experimental conditions. Comparisons were conducted on both number of correct answers and PAE.

Percent Correct on Trained Addition Problems

A 2 (computer-generated magnitude representations: present or absent) × 2 (child-generated magnitude representations: present or absent) × 2 (time of test: pretest or end of training) analysis of variance (ANOVA) on the number of correct answers was conducted to determine whether the visual representations of numerical magnitude influenced children's learning up to the end of training. The analysis yielded main effects for the time of test variable, $F(1, 101) = 70.14$, $p < .01$, $\eta^2 = .41$, and for exposure to computer-generated visual representations, $F(1, 101) = 4.08$, $p < .05$, $\eta^2 = .04$. Children generated more correct answers at the end of training than on the pretest (29% vs. 7%) and children who encountered the accurate, computer-generated representations of numerical magnitudes generated a greater number of correct answers than did children who did not encounter them (21% vs. 15%).

The interaction among the three variables also was significant, $F(1, 101) = 5.01$, $p < .05$, $\eta^2 = .05$. To interpret this interaction, we first conducted separate ANOVAs for pretest and end-of-training performance. No differences among the four groups were apparent on the pretest, $F(3, 101) = 1.02$, *ns*, $\eta^2 = .03$, but differences were present at the end of training, $F(3, 101) = 2.62$, $p = .05$, $\eta^2 = .07$. Fisher's least significant difference (LSD) post hoc tests indicated that at the end of training, children in the *computer generate* condition advanced a greater number of correct answers than peers in both the *control* and the *child and computer generate* conditions (*ps* < .05, *ds* = 0.75 and 0.61, respectively). These findings indicated that the interaction was due to the *computer generate* procedure increasing learning when presented alone but not when presented in combination with the *child generate* procedure.

Analyses of pretest–posttest changes for each of the four groups supported this interpretation. As shown in the top half of Table 4, children in all four groups answered correctly more often at the end of training than on the pretest: *control*, $t(26) = 3.43$, $p < .01$, $d = 0.88$; *child generate*, $t(25) = 4.41$, $p < .01$, $d = 1.22$; *computer generate*, $t(25) = 6.53$, $p < .01$, $d = 1.51$; and *child and computer generate*, $t(27) = 2.67$, $p < .01$, $d = 0.65$. However, the changes were larger in the *computer generate* condition (32% difference between pretest and posttest percent correct) than in the other three conditions (15%, 17%, and 24%).

A parallel 2 × 2 × 2 ANOVA on changes in correct answers between pretest and follow-up on the training problems indicated only a single main effect for time of testing, $F(1, 101) = 7.96$, $p < .01$, $\eta^2 = .07$. Children advanced a greater number of correct answers at the follow-up than at the pretest (13% vs. 7%).

PAE on Trained Addition Problems

To determine whether encountering accurate visual representations of the magnitudes of the addends and sum influenced the quality of students' errors as well as the frequency of correct answers, we conducted a 2 (computer-generated magnitude representations: present or absent) × 2 (child-generated magnitude representations: present or absent) × 2 (time of testing: pretest or end of training) ANOVA on PAE on the addition problems. As on the parallel analysis of correct answers, the ANOVA revealed a main effect for time of testing, $F(1, 101) = 6.59$, $p < .01$, $\eta^2 = .06$. From the pretest to the end of training, PAE on the addition problems dropped from 16% to 13%.

Table 4

Percent Correct and PAE for Trained Addition Problems on Pretest, End-of-Training, and Follow-Up Sessions

	Pretest	End of training	Follow-up
Percent correct			
Control	6 (13)	23 (24)	10 (16)
Child generate	4 (12)	28 (25)	13 (20)
Computer generate	9 (18)	41 (24)	13 (22)
Child and computer generate	10 (17)	25 (28)	14 (9)
PAE			
Control	18 (10)	16 (12)	18 (11)
Child generate	17 (12)	12 (9)	16 (13)
Computer generate	15 (11)	9 (9)	13 (10)
Child and computer generate	14 (9)	15 (10)	14 (9)

Note. All statistics are reported as *M* (*SD*). PAE = percent absolute error.

Also as on the parallel analysis of changes in correct answers, the ANOVA for the PAE data revealed an interaction among the three variables, $F(1, 101) = 4.36$, $p < .05$, $\eta^2 = .04$. The source of the interaction appeared to be the same as in the analysis of correct answers. Again, no differences among the four groups were detected on the pretest, $F(3, 101) = 0.62$, *ns*, $\eta^2 = .02$, but the groups tended to differ at the end of training, $F(3, 101) = 2.12$, $p = .10$, $\eta^2 = .06$. LSD post hoc tests indicated that children in the *computer generate* condition had a lower posttest PAE than peers in the *control* condition ($p < .05$, $d = 0.66$), and tended to have a lower posttest PAE than children in the *child and computer generate* condition ($p < .10$, $d = 0.63$).

Analyses of pretest–posttest changes for each of the four groups supported this interpretation (bottom half of Table 4). Children in the *computer generate* group reduced their PAE on the trained addition problems between the pretest and the end of training, $t(24) = 2.13$, $p < .05$, $d = 0.60$. There was also a trend toward reduced error for children in the *child generate* group between the pretest and the end of training, $t(25) = 1.88$, $p < .10$, $d = 0.47$. In contrast, PAE did not decrease either in the *child and computer generate* group, $t(26) = 0.32$, *ns*, $d = 0.11$, or in the *control* group, $t(26) = 0.84$, *ns*, $d = 0.18$.

A parallel 2 × 2 × 2 ANOVA on changes in PAE between pretest and follow-up on the training problems yielded no significant main effects or interactions.

Numerical Magnitude Estimation

Exposure to visual representations of numerical magnitudes was also expected to improve children's number line estimates because of the training providing experience with number line representations of numerical magnitudes. Separate 2 (computer-generated magnitude representations: present or absent) × 2 (child-generated magnitude representations: present or absent) × 2 (time of testing: pretest or end of training) ANOVAs were performed on PAE and linearity (R^2_{Lin}) of number line estimation.

Main effects of viewing computer-generated visual representations were found on PAE, $F(1, 100) = 7.23$, $p < .01$, $\eta^2 = .07$. The number line estimates of children who encountered accurate, computer-generated representations had a lower PAE than did peers who did not encounter the accurate visual representations (9% vs. 11%).

In addition to this main effect, an interaction between exposure to computer-generated representations and test session was present on the PAE measure, $F(1, 100) = 4.87$, $p < .05$, $\eta^2 = .05$. The number line estimates of children who viewed the computer-generated (correct) visual representations improved from a PAE of 10% on the pretest to 9% at the end of training. In contrast, the number line estimates of peers who did not see correct visual representations of numerical magnitude failed to improve: PAE increased from 11% to 12%.

Discussion

The results of this study supported three of the four hypotheses that motivated it. As hypothesized, the linearity of children's number line estimates correlated positively with their existing knowledge of addition. Also as hypothesized, the degree of linearity of children's pretest estimates was predictive of their learning of answers to novel addition problems. Moreover, providing accurate visual representations of the magnitudes of addends and sums increased children's learning of the novel addition problems beyond the level produced by simply presenting problems and answers. The one result that was contrary to expectation was that having children generate their own representations of addends and sums did not enhance learning and may have interfered with it. In this concluding section, we examine implications of these findings for understanding the role of numerical magnitude representations in childhood numerical competence, for understanding arithmetic learning, and for improving mathematics instruction.

Numerical Representations and Numerical Competence

The pretest results both replicated and extended previous findings that the linearity of elementary schoolchildren's representations of numerical magnitudes is related to their performance on a wide range of numerical tasks. Prior studies indicated that the linearity of number line estimates correlates positively with the linearity of measurement estimation, numerosity estimation, numerical categorization, and numerical magnitude comparison as well as with math achievement test scores (Booth & Siegler, 2006; Laski & Siegler, 2007; Siegler & Booth, 2004.) A very recent study added the findings that preschoolers' estimates on a 0–10 number line correlate positively and quite strongly with their counting, numeral identification, and magnitude comparison skills (Ramani & Siegler, 2008).

The present study replicated the relation of number line estimation to standardized achievement scores in those studies and indicated that first graders' linearity of numerical magnitude representations also is related to their arithmetic proficiency and short-term memory for numbers. Two other very recent studies have linked the linearity of number line estimation to yet other aspects of cognition: several measures of executive functioning and IQ test scores (Geary, Hoard, Nugent, & Byrd-Craven, in press; Geary et al., 2007). Geary and his colleagues advanced the intriguing hypothesis that the strong relations of executive functioning to linearity of number line estimates reflect the need for children to inhibit the previously dominant logarithmic representation when they begin to rely on the linear representation. Geary and colleagues' (Geary et al., 2007; Geary et al., in press) research also demonstrated that the number line estimates of first and second graders diagnosed as having math learning disabilities lag far behind those of typically achieving peers in both linearity and accuracy.

Taken together, the present and previous findings indicate that preschoolers' through fourth graders' numerical magnitude representations are positively correlated with performance on specific tasks measuring a wide range of specific numerical competencies as well as with performance on overall tests of mathematical achievement and IQ. The linearity of the numerical magnitude representations also shows robust and stable patterns of individual differences and consistent developmental trends (Booth & Siegler, 2006; Geary et al., 2007). Thus, as hypothesized by Case and colleagues (Case, 1992; Case & Okamoto, 1996; Griffin, Case, & Sandieson, 1992; Marini, 1992), the mental number line appears to provide a central conceptual structure for organizing a wide range of numerical knowledge.

Arithmetic Learning

The present findings indicated that numerical magnitude representations are not only positively related to a variety of types of numerical knowledge but also predictive of success in acquiring new numerical information, in particular, answers to arithmetic problems. Prior studies (e.g., Geary et al., 2007; Jordan et al., 2006) had shown that incoming characteristics of students predict their learning of arithmetic and other numerical skills during the school year. However, the present study appears to be the first to demonstrate that such predictive relations are present when learning occurs under experimentally controlled conditions.

An important implication of the present findings is that arithmetic learning, even in the sense of memorizing answers to unfamiliar problems, is not a rote activity but rather a meaningful one. If memorization of answers to arithmetic problems were a rote activity, there would be no reason to expect that being presented accurate visual representations of the magnitudes of addends and sums would increase learning of correct answers. Nor would there be any reason to expect that pretest linearity of number line estimation would predict learning of novel arithmetic problems, even after prior knowledge of arithmetic, short-term memory for numbers, and overall math achievement test scores were statistically controlled. These results cannot be explained in terms of exposure to the addends and answers, which were the same in all four conditions, nor in terms of time on task, which was greater for children generating their own representations of numerical magnitudes than for children who encountered the computer-generated accurate ones.

Several previous investigators have argued that backup strategies, such as counting fingers, counting from the minimum addend, and repeated addition, make arithmetic a meaningful activity (Brownell & Chazal, 1935; Cowan, 2003; Cowan, Dowker, Christakis, & Bailey, 1996; Cowan & Renton, 1996). The present findings add evidence that linear representations of numerical magnitudes make arithmetic meaningful even when children learn answers via retrieval.

Although the linearity of numerical magnitude representations on the pretest was related to improvements on the trained arithmetic problems in both percent correct and PAE, the relations to reductions in PAE were stronger, accounting for more than twice as much variance both at the end of training and at the follow-up. This finding was consistent with the theory underlying the experiment. The most straightforward way in which numerical magnitude representations would influence arithmetic learning is by constraining the set of possible answers to ones of approximately the right magnitude. Such constraints would have the direct effect of improving the quality of errors; they also would increase the likelihood of the exact correct answer because, by definition, it has exactly the right magnitude.

Linearity of numerical magnitude representations was not the only type of numerical knowledge that predicted arithmetic learning. Mathematical achievement test scores and addition knowledge also did. Yet, linearity of magnitude representations was predictive of arithmetic learning even after the relations of the other variables to arithmetic learning were statistically controlled. The question was why.

Our interpretation is that linearity of number line estimates varies more closely with the underlying variable of linearity of numerical magnitude representations than do the other two variables. Addition knowledge and achievement test scores vary in part with linearity of numerical magnitude representations, but they also vary with other influences (e.g., counting skills, memory for computational procedures, and short-term memory for numbers). Thus, linearity of number line estimation may predict learning of novel arithmetic problems above and beyond the prediction of the other variables because it provides a purer measure of the underlying magnitude representation.

The present findings ruled out the possibility that the predictive relation of linearity of number line estimation to arithmetic learning simply reflected general familiarity with numbers or the richness of the home intellectual environment. If either of these interpretations were correct, there would be no reason to expect that linearity of number line estimates would remain a significant predictor of learning of novel arithmetic problems even when achievement test scores and prior addition knowledge were statistically controlled. Indeed, there was reason to expect the opposite. Some parents teach their young children to solve arithmetic problems, whereas others do not. First graders' knowledge of addition would be expected to reflect this parental input. In contrast, to the best of our knowledge, no parents (not even the present authors) are so pedantic that they ask their children to locate numbers on number lines. Thus, the fact that the linearity of number line estimation predicts arithmetic learning above and beyond prior arithmetic knowledge indicates that learning of new arithmetic problems is influenced by numerical magnitude representations.

The one factor that, to our surprise, did not predict learning of addition facts was short-term memory for numbers. One possible explanation is that the training in this study allowed children to view the addends and the answers simultaneously as they were trying to learn them; thus, the task format may have reduced the burden on short-term memory of learning answers to arithmetic problems. Another possible explanation was that the digit span task was an inadequate measure of short-term memory capacity; a measure of working memory might have revealed stronger relations.

Instructional Implications

Results of the experimental manipulations yielded causal evidence that converged with the correlational data. As hypothesized, exposure to accurate visual representations of numerical magnitude improved children's arithmetic learning. This was true both when learning was measured in terms of percent correct and when it was measured in terms of PAE. Thus, the patterns of correlations on the pretest, the predictive relations from pretest performance to performance at the end of training, and the effects of providing randomly chosen children with accurate linear representations of numerical magnitude converged on the conclusion that linear representations of numerical magnitude promote arithmetic learning.

Self-generated representations of numerical magnitudes did not have a comparable effect. In fact, they appeared to interfere with the positive effects of being shown accurate visual displays when children received both. Thus, it appears that pictorial representations of numerical magnitudes must be accurate to enhance learning. The pattern of results dovetails with previous findings, indicating that being asked to explain correct answers improves learning of mathematical and scientific information, but being asked to explain the reasoning underlying ones' own answers, right or wrong, does not enhance learning (Siegler, 1995, 2002).

Perhaps the most surprising finding of the study was that the combination of computer-generated and self-generated magnitude representations was less effective in promoting learning than the computer-generated representations alone. One plausible interpretation was that the first graders in this condition simply could not take in all of the information when both representations were present. Seeing both visual representations on the screen may have provided a difficult source monitoring challenge in that it required remembering that the computer-generated representations were the accurate ones and that the self-generated ones were not necessarily accurate. Source monitoring is generally a difficult task for young children (Ratner, Foley, & Gimpert, 2002). The challenge might have been especially great in the current context because the correct interpretation required children to discount their own magnitude estimates.

The pattern of effects and noneffects in the present study highlights the value of presenting accurate visual representations of mathematical relations. Contemporary mathematics education for elementary schoolchildren makes a great deal of use of concrete objects that can be manipulated, such as Dienes Blocks and Cuisenaire Rods. Recent research, however, suggests that children often have difficulty viewing physical objects purely as symbols, even when that is the teacher's intent. This is especially the case when children handle or play with the objects (DeLoache & Burns, 1994; Uttal, Liu, & DeLoache, 2006).

The findings and analyses of DeLoache, Uttal, and their colleagues (DeLoache & Burns, 1994; Uttal et al., 2006), along with the present findings, provide a basis for hypothesizing that accurate pictorial representations, such as diagrams and graphs, may be particularly useful for promoting math learning. Like manipulatives, they provide a visual representation of the meaning of mathematical operations. Unlike manipulatives, they are not tempting objects for play and other activities that may interfere with their connection to mathematical operations. This analysis, together with the present finding that accurate visual representations of numerical magnitude promote arithmetic learning, suggests that providing pictorial information that illustrates mathematical relations in a transparent way can improve math learning as early as first grade.

Investigating the Development of Data Evaluation: The Role of Data Characteristics

Amy M. Masnick
Hofstra University

Bradley J. Morris
Grand Valley State University

A crucial skill in scientific and everyday reasoning is the ability to interpret data. The present study examined how data features influence data interpretation. In Experiment 1, one hundred and thirty-three 9-year-olds, 12-year-olds, and college students (mean age = 20 years) were shown a series of data sets that varied in the number of observations and the amount of variance between and within observations. Only limited context for the data was provided. In Experiment 2, similar data sets were presented to 101 participants from the same age groups incrementally rather than simultaneously. The results demonstrated that data characteristics affect how children interpret observations, with significant age-related increases in detecting multiple data characteristics, in using them in combination, and in explicit verbal descriptions of data interpretations.

One crucial skill in scientific and everyday reasoning is the ability to interpret data. For example, imagine two golfers on a driving range hit three balls each. Golfer A hits the balls 100, 130, and 125 yards, whereas Golfer B hits the balls 250, 265, and 270 yards. If asked to predict which golfer would likely hit the ball farther on the next drive, an observer would probably pick Golfer B. It is likely that our observer would not treat each drive as an unrelated incident but would see each drive as one piece of data related to a stable underlying construct (e.g., skill in driving a golf ball). Along with this understanding is an expectation that even when such a construct is stable, there is variation in outcomes (i.e., exact distance of drive). Although the mechanism causing the difference might not be clear to the observer (e.g., strength, practice), the resulting pattern of observations suggests nontrivial differences between the performances of the two golfers. Explanations for the difference in performance (i.e., specifying causal mechanism) would arise from a combination of the observer's background knowledge and the data.

Although such inferences may be trivial for adults, children often err when making similar comparisons (see Zimmerman, 2000, 2007, for reviews). One source of difficulty is that children tend to rely heavily on their domain knowledge when interpreting data, even to the extent of ignoring disconfirming data that conflict with their current knowledge or expectations (e.g., Chinn & Malhotra, 2002; Kuhn, Garcia-Mila, Zohar, & Andersen, 1995; Schauble, 1996). For example, when children observed the speed of two falling objects that differed in size or weight, their prior beliefs that the objects would fall at different speeds affected both their observations and conclusions from the data. Thus, after viewing two objects released at the same time from the same height, many children claimed that they had observed one object fall faster than the other, despite the fact that they fell at the same rate (Chinn & Malhotra, 2002).

Many investigations of children's data interpretation have done so within knowledge-rich domains (e.g., Echevarria, 2003; Metz, 2004). However, children often encounter situations about which they have very limited background knowledge. In these

situations, data provide a rich source of information from which to draw conclusions about a phenomenon. What is not known is whether children attend to and use particular diagnostic features of data. That is, given a set of observations, are there properties of data sets—unrelated to knowledge of the domain—that help reasoners induce trends from data sets without using formal statistics?

We suggest that two diagnostic features of data patterns may play an important role in reasoning: sample size and variability. Sample size refers to the number of observations within a data set. Considering the golfing example mentioned previously, someone using sample size as a factor to assess differences between two golfers would likely be more confident about drawing conclusions with more data available (e.g., three hits per golfer vs. one hit per golfer). Variability refers to the degree of similarity or dissimilarity among values within and between the set of observations. Returning to the golfing example, *within-group* variability is a measure of differences in the outcomes of drives made by the same golfer, whereas *between-group* variability is a measure of differences in drives between golfers. A reasoner using variability characteristics of data would be more confident of conclusions drawn from data as the variability within a set of observations decreases and variability between a set of observations increases.

Reasoning About Data in Category Induction and Scientific Reasoning Tasks

In category membership tasks, there is evidence that elementary school children recognize sample size and variability. Gutheil and Gelman (1997) found that although adults used variability and sample size in combination or independently, 8- and 9-year-old children did not differentiate between sets of exemplars that differed only in sample size or in variability but did differentiate when both sample size and variability differed between sets. In related work, Jacobs and Narloch (2001) asked children in Grades 1, 3, and 5 to predict how common a trait would be in a given population based on a sample that varied in number (sample size) and homogeneity (within-group variability). Prior knowledge about variability affected children's predictions more than sample size. Strong prior assumptions about the phenomena in question influence reasoning about data characteristics.

There is also evidence that children attend to sample size and data variability in scientific reasoning contexts. Piaget and Inhelder (1951/1975) investigated children's assessments of the probability of a spinner landing in a series of possible locations. By middle childhood, children's judgments about future landing sites were related to the number of previous observations, indicating some understanding of sample size (i.e., the law of large numbers, or the idea that larger sample sizes make one more confident about generalizing to a population). Klaczynski and Aneja (2002) also demonstrated that children as young as 7 years old applied the law of large numbers in inferring new gender stereotypes by being more confident when shown a larger sample than a small one.

A very common scientific reasoning task involves drawing conclusion based on the evaluation of covariation data (e.g., Koerber, Sodian, Thoermer, & Nett, 2005; Kuhn, Amsel, & O'Loughlin, 1988; Shaklee & Paszek, 1985). Interpreting covariation data is also influenced by data characteristics. Koslowski, Okagaki, Lorenz, and Umbach (1989) asked sixth-grade, ninth-grade, and college participants whether a target factor was likely to cause a particular effect (e.g., whether using a gasoline additive leads to worse gas mileage). Information presented to participants varied in sample size and in whether there was evidence of covariation. Without covariation information, all participants differentiated between large and small sample sizes; however, with covariation information, only the college students used sample size information. Thus, there is evidence that sixth and ninth graders have some difficulty integrating multiple characteristics of the data. At the same time, even sixth graders can use sample size in the absence of other information to infer cause. Koslowski (1996, Experiment 10) also reported that when more instances of covariation were present, participants were more likely to rate the association between two variables as causal than when there was only one instance of covariation.

Children also attend to variability within and between data sets. When second and fourth graders rolled two balls down two ramps and measured the distance each traveled, they distinguished between the small differences expected in individual data points (within-group variability) and larger differences expected between groups (between-group variability; Masnick & Klahr, 2003). The expectation that there will be some variation in precise data points indicates an understanding that many factors affect the outcome of an experiment, even when these small differences may not affect overall conclusions.

Yet, there is evidence that children have difficulty understanding what this variability indicates. Lubben and Millar (1996) showed 11-, 13-, and 15-year-olds two sets of results with equal means but different amounts of variation. Participants were asked whether one set of results was more trustworthy or if they were equally trustworthy. About half (47% – 55%) of all participants said that one data set was more trustworthy than the other. However, only about 20% of 11-year-olds justified their choice by referring to variation in the data. Forty-four percent of 13-year-olds and 48% of 15-year-olds justified their choice by referring to variation in data, indicating an understanding that data variability is a component of assessing reliability (Lubben & Millar, 1996). Thus, even into high school, a sizable number of students have difficulty using variability information in drawing conclusions.

Studies of covariation detection, in effect, ask participants to assess an "intuitive chi-square" estimate: How likely is it that the observed pattern of frequencies occurred by chance? Although much of the research on the evaluation of evidence has taken the form of covariation matrices concerning the frequency of the presence and absence of putative causes and effects (i.e., an intuitive chi-square, as in Shaklee & Paszek, 1985), in both real-world contexts and the science classroom, children must evaluate the differences in a range of *quantitative* data. Zimmerman (2000) noted that to determine if a specific antecedent is linked with an outcome, one compares the number of times the outcome occurs or does not occur when the antecedent is present. If the former is much larger than the latter, one can generally conclude that there is a relationship between the two. However, she observed that "it is not clear *how large* the difference must be in order to conclude that the two events are related" (p. 115). The question is then, How do students reason when comparing sets of quantitative data?

In addition to the evidence that elementary and secondary school children attend to features of data in some contexts, there is also evidence that very young children have some fundamental understanding of relative quantity. Even 6-month-old infants can accurately compare two quantities (see Feigenson, Dehaene, & Spelke, 2004, for a discussion), and 5-year-old children are equally adept at determining which quantity is larger when presented Arabic numerals or arrays of dots (Temple & Posner, 1998). Thus, it seems possible that some of the skills required for effective data comparison are implicit and not the result of direct training. It is possible that children use a relatively automatic process of quantity comparison. We follow Rubinsten, Henik, Berger, and Shahar-Shalev (2002) in suggesting that "automatic" refers to processing that requires no conscious monitoring after commencing. The process that operates may be an "intuitive" statistical test on data patterns. We use the term "intuitive" to convey the automaticity of the process.

Clearly, comparing sets of data requires processing beyond that of simply detecting differences in magnitude. A second set of processes is needed to process exact differences (e.g., perform calculations), to examine characteristics of data, and to integrate this information with domain knowledge. Inhelder and Piaget (1958) suggested that a pattern of fixating on one feature instead of looking at features in concert was the source of young children's difficulty in solving conservation tasks. If children do focus initially on a small number of features, then we would expect to see age-related increases in the number of characteristics to which they attend. Additionally, children would likely develop the ability to compare sets along multiple dimensions before they could explicitly access knowledge to consider each variable independently within the set. It is likely that these improvements are due to many factors including acquisition of new strategies, increases in domain knowledge, and increases in processing capacity (Halford, Cowan, & Andrews, 2007).

Present Study

To our knowledge, there has been no systematic investigation of the characteristics of data to which children attend and to what extent these characteristics influence their judgments about phenomena. The present study was designed to examine which characteristics of data guide inferences when comparing data sets. First, we predicted that sample size is likely to play an important role in reasoning. Second, we predicted that in drawing conclusions about comparative data, two characteristics that indicate the *amount of variation* in the data are key: within-group variability (i.e., the variability of the data points relative to mean) and between-group variability (i.e., variability of data points in each of two data sets relative to one another). This information about variability can be assessed increasingly well with a larger sample size of data points. Finally, we predicted that with age, children will become better at using multiple characteristics of data in concert and will have more explicit understanding of the importance of these characteristics for making judgments about quantitative data.

We chose to work with third- and sixth-grade students to explore developmental changes through elementary school because past work on reasoning with data has often examined children in these age groups (e.g., Gutheil & Gelman, 1997; Inhelder & Piaget, 1958; Jacobs & Narloch, 2001; Koslowski et al., 1989), as they become exposed to experimental data in school. Our pilot data indicated that third graders were the youngest age group in which all participants could consistently perform our data interpretation tasks. A 3-year age difference allows for a large enough difference to see change if it is apparent. We chose a college student comparison population because it is clear that these skills continue to develop with experience and age.

In two experiments, children and college students were presented with sets of paired data and asked to draw conclusions about differences between the sets. In Experiment 1, data were presented with one of two framing stories that limited the amount of background knowledge that could be brought to bear in drawing conclusions about the data. The data presented varied systematically in number of data points presented, within-group variability (operationalized as a dichotomous variable, with two sizes of standard deviations relative to the mean), and between-group variability (operationalized as the number of pairs of data in which the data point from the column with the lower mean was higher than the data point from the column with the higher mean).

When studying reasoning about any topic, it is important to consider both implicit and explicit evidence of knowledge used. Nisbett and Wilson (1977) argued that explicit justifications for behaviors are often distinct from actual reasons for behavior and that the salience of a stimulus is the key determinant of it being used as a justification. Thus, a full understanding of the cognitive process involves looking at both patterns of conclusions drawn from data and explicit rationales for these patterns. Participant responses were analyzed to examine how each of the three characteristics of data (sample size, between-group variability, and within-group variability) was used in implicit and explicit reasoning.

Experiment 1

Method

Participants. Thirty-nine third graders (mean age = 9.1 years, range = 8.2 – 10.3 years), 44 sixth graders (mean age = 11.9 years, range = 11.2 – 12.8 years), and 50 college undergraduates (mean age = 20.2 years, range = 18.1 – 23.7 years) participated in this study. College students were recruited from undergraduate psychology courses, and younger participants were recruited from letters sent to parents at four elementary and middle schools in the northeast United States. The third-grade sample consisted of 92% White students, 5% Black students, and 3% Hispanic students. The sixth-grade sample consisted of 82% White students, 2% Asian students, and 16% Black students. The college student sample consisted of 54% White students, 40% Asian students, 2% Black students, and 4% Hispanic students.

Procedure. All participants were interviewed individually. Participants were randomly assigned to one of two cover story conditions: one in which robots were the source of the data and one in which athletes (people) were the source of the data. In the robot condition, each participant was read the following information:

> Some engineers are testing new sports equipment. Right now, they are looking at the quality of different sports balls, like tennis balls, golf balls and baseballs. For example, when they want to find out about golf balls, they use a special robot launcher to test two balls from the same factory. They use a robot launcher because they can program the robot to launch the ball with the same amount of force each time. Sometimes they test the balls more than once. After they run the tests, they look at the results to see what they can learn.

In the athlete condition, we used an isomorphic cover story in which two athletes were trying out for one slot on a sports team. The coaches asked the participants to perform certain tasks (e.g., hit a golf ball as far as possible) to assess which athlete would be better for the team. For example, participants in the athlete condition saw the following story: "Harriet and Joan are trying out for the soccer team. The soccer coach asked them to kick a soccer ball four times. The coach measured how far the soccer ball went each time it was kicked." This cover story was designed to see if adding information about a potential source of variability (human error) would change participants' responses. Thus, the robot condition presented a cover story that minimized potential sources of variability, whereas the athlete condition provided potential sources of variability.

After reading the cover story, the participants were shown a series of 14 data sets, one at a time. For each data set, there were data either for two balls of the same type, with no distinguishing characteristics (e.g., Baseball A and Baseball B), or for two athletes, with no information other than first names (e.g., Alan and Bill). The 14 balls tested were golf balls, racquetballs, basketballs, soccer balls, ping pong balls, footballs, volleyballs, baseballs, tennis balls, marbles, hockey pucks, kickballs, softballs, and bowling balls. Participants were randomly assigned to one of two orders of presentation. There were no order effects; therefore, results are collapsed across order. In the athlete condition, different names were used for each data set to prevent any carryover knowledge effect.

For each data set, there were one, two, four, or six pairs of data. Each page contained two columns of data: one column listing the distance the first ball traveled and one listing the distance the second ball traveled. (See Table 1 for specific examples of the different data characteristics.)

The 14 data sets varied in (a) sample size, (b) between-group variability (i.e., reversals in which column's number was higher), and (c) within-group variability (i.e., high or low variability relative to the means). Each participant evaluated 14 comparisons, with eight trials including no reversed pairs (sample sizes 1, 2, 4, and 6) and six trials including one or two reversed pairs (sample size 4 with one reversed pair, and sample size 6 with one and two reversed pairs). Half of the trials had high within-group variability, in which the standard deviation of the data set was 15% – 20% of its mean, and half had low within-group variability, in which the standard deviation of the data set was less than 2% of its mean. Each of the 14 trials tested a different type of sports ball.

For each data set, participants were asked first what the engineer or coach could find out as a result of this information and to explain any reasons for their answer. Next, they were asked how sure they were about these conclusions. To answer the questions about sureness, participants were offered a 4-point scale from which to select their answer, choosing among *not so sure*, *kind of sure*, *pretty sure*, and *totally sure*.

Measures. For each question in which participants were asked to report their conclusions and predictions, and their confidence in their answers, participants first answered yes or no and then rated their confidence on a 4-point Likert scale. These two responses—yes – no and sureness level—were combined into a single 7-point ordinal variable: *totally sure there is a difference*, *pretty sure there is a difference*, *kind of sure there is a difference*, *not so sure* (regardless of yes or no answer), *kind of sure there is no difference*, *pretty sure there is no difference*, *totally sure there is no difference.* Past research has demonstrated that the children as young as 8 years old have been able to understand and work with such a scale (Masnick & Klahr, 2003). Participants were asked to provide reasons for their initial conclusions and final predictions of relative position. These reasons were coded for mention of data characteristics (such as sample size or variability) or mechanism (such as a property of the ball that could have affected the results).

Table 1
Examples of Data Sets in Experiment 1

Example 1: Six data pairs with one reversed data pair (five of six times Basketball B goes farther), high within-group variability, robot condition

Basketball A	Basketball B
56 ft	74 ft
65 ft	83 ft
75 ft	57 ft
49 ft	66 ft
48 ft	67 ft
64 ft	82 ft

Example 2: Two data pairs with no reversed pairs, low within-group variability, athlete condition

Joan	Harriet
372 ft	383 ft
363 ft	374 ft

Results

The main research question was whether different types of data patterns and different contexts affect participants' decisions about, and confidence in, their judgments of whether there is a difference between the two groups of data presented. Decisions about whether the data sets differed were operationalized by participants' responses to whether they thought the engineer or coach could be sure that there was a difference between the two groups. In addition, participants' reasons for the responses were analyzed.

Use of data characteristics to judge whether there was a difference between the data sets. For each assessment, sample size, between-group variability (number of reversed pairs), and within-group variability (spread) were within-subjects variables, and cover story was a between-subjects variable. There were no gender differences. In addition, for the college students, there were no differences in ratings for those who had taken different numbers of statistics classes. Thus, these two variables were not considered in later analyses. Because the data were not set up in a full factorial design, each data characteristic was analyzed separately. Of those who said that one ball traveled farther than the other, third graders were accurate in stating which ball went farther 92.4% of the time, sixth graders were accurate 98.8% of the time, and college students were accurate 99.5% of the time.

A 4 (sample size: 1, 2, 4, or 6) × 3 (age: third grade, sixth grade, or college) × 2 (cover story: robot vs. athlete) mixed analysis of variance (ANOVA) was used to assess whether sample size influenced confidence judgments in cases with no between-group variability. There was a main effect of sample size, $F(3, 120) = 20.68$, $p < .001$, partial $\eta^2 = .34$; a main effect of age, $F(2, 122) = 44.52$, $p < .001$, partial $\eta^2 = .42$; no main effect of cover story, $F(1, 122) = 0.70$, $p > .1$; and a Sample Size × Age interaction, $F(6, 240) = 17.63$, $p < .001$, partial $\eta^2 = .31$ (Figure 1). Tukey's honestly significant difference (HSD) post hoc tests indicated that college students' ratings were significantly lower on average than the third and sixth graders'. College students' sureness ratings increased dramatically with sample size, $F(3, 44) = 50.59$, $p < .001$, partial $\eta^2 = .78$, and sixth graders' ratings increased a small but significant amount with increased sample size, $F(3, 38) = 3.33$, $p = .030$, partial $\eta^2 = .21$. Third graders, in contrast, showed a slight trend of *decreased* sureness ratings with increased sample size, $F(3, 34) = 2.26$, $p = .099$, partial $\eta^2 = .17$. There were no interactions with the cover story. In sum, at all age levels, it was apparent that participants were sensitive to differences in sample size. For sixth graders and college students, this observation tended to increase ratings of sureness; for third graders, it tended to decrease ratings.

In addition to sensitivity to sample size, we also explored sensitivity to the presence of reversed data pairs (between-group variability) by examining only the data sets with six pairs of data. This pattern occurred when there were no reversed data pairs, one reversed pair, and two reversed pairs. A 3 (between-group variability: zero, one, or two pair reversals) × 3 (age: third grade, sixth grade, or college) × 2 (cover story: robot vs. athlete) mixed ANOVA demonstrated no effect of cover story, $F(1, 123) = 0.56$, $p > .1$. There was a main effect for between-group variability (lower sureness ratings with more variability), $F(2, 122) = 53.15$, $p < .001$, partial $\eta^2 = .47$; a main effect for age (higher average ratings for third graders than for sixth graders and college students), $F(2, 123) = 9.59$, $p < .001$, partial $\eta^2 = .14$; and a Variability × Age interaction, $F(4, 244) = 4.70$, $p = .001$, partial $\eta^2 = .07$ (Figure 2). At all age levels, participants' mean sureness ratings decreased with more reversed data pairs between the two groups of data, with the effect stronger with increasing age: for third graders, $F(2, 34) = 3.51$, $p = .041$, partial $\eta^2 = .17$; for sixth graders, $F(2, 40) = 14.42$, $p < .001$, partial $\eta^2 = .42$; and for college students, $F(2, 46) = 68.15$, $p < .001$, partial $\eta^2 = .75$.

We also assessed differences in within-group variability (data spread) on ratings of confidence that there was a difference between the two data sets. Participants saw two data sets with each sample size and between-group variability combination used (e.g., two data pairs with no reversed pairs; six data pairs with one reversed pair). One of these data sets had high within-group variability (standard deviation between 15% and 20% of mean) and one had low within-group variability (standard deviation less than 2% of mean). We calculated a paired t test for each sample size/between-group variability combination participants saw (directly comparing sureness ratings from data with high and low within-group variability). Third and sixth graders showed no evidence of differentially rating data sets based on within-group variability. College students had an inconsistent pattern, in which three of the six comparisons reached significance (for four pairs with no reversed pairs, for six pairs with one reversed pair, and for six pairs with two reversed pairs). Surprisingly, in each of these comparisons, participants were more sure in the case with *higher* variability. Possible explanations for this pattern are proposed in the Experiment 1 Discussion section.

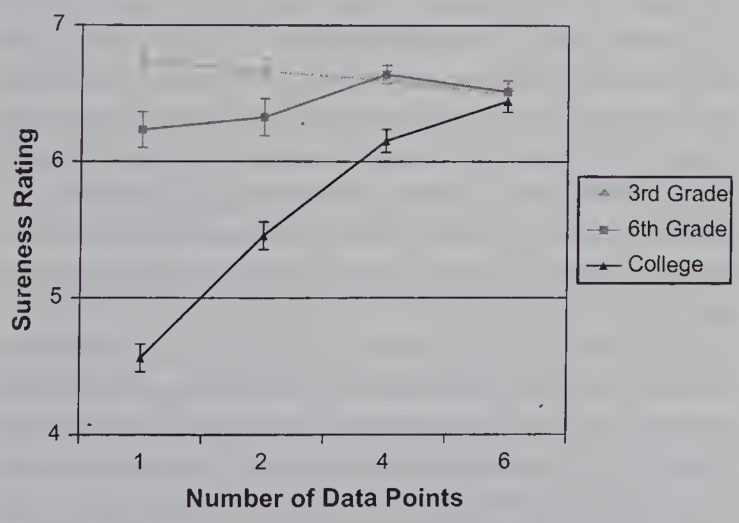

Figure 1. Experiment 1: Participants' sureness ratings at each grade with one, two, four, and six pairs of data but no reversed data pairs (collapsed across cover story).
Note. Error bars represent standard error of measurement.

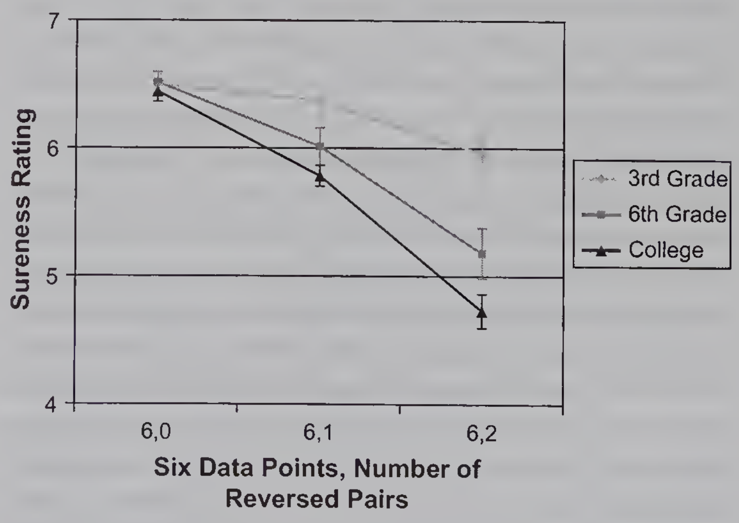

Figure 2. Experiment 1: Participants' sureness ratings at each grade with six pairs of data, by level of between-group variability in the data (collapsed across cover story).
Note. Error bars represent standard error of measurement.

When people evaluate differences between sets of data, they do not focus on only one characteristic. For example, in computing formal statistics, a *t* statistic takes account of both sample size and variability when testing for significant differences between means. The next analysis explored the possibility that our participants used an "intuitive *t* test" in which a combination of the number of data points and the variability of the data points were both considered in evaluating differences between means. Although these are small data sets, we calculated the independent *t*-test statistic for each set of data presented to the participants to examine the trends (with the obvious exception of the two sets with one pair). These 12 *t* values ranged from 0.88 to 4.18. Next, we correlated the *t* statistics for the presented data with the mean sureness rating participants gave assessing whether there was a difference between the two sets of data, by grade. An interesting pattern emerged. Third graders' ratings were not significantly associated with the independent *t* statistic ($r = .388, p = .213$), sixth graders' ratings showed evidence of a strong relationship ($r = .632, p = .028$), and college students showed evidence of a very strong relationship ($r = .873, p < .001$).

Reasons offered. Participants offered explicit justifications for confidence or lack thereof in their conclusions and for the predictions they made about which ball would go farther on a subsequent trial. Reasons given were coded for mention of the manipulated data characteristics: (a) sample size, (b) between-group variability (whether the data sets included pair reversals or not), and (c) within-group variability (spread of the data). We also noted mention of (d) a trend in the data and (e) the magnitude of the difference between the two data sets. Additionally, explanations of how the outcome could have occurred were coded, including (f) a property of the ball that affected the results, (g) a property of the robot or athlete that affected the results, or (h) a property of the environment—other than the ball, robot, or athlete—that affected the results. The categories were not mutually exclusive, and participants had 28 opportunities to explain their reasoning (twice for each of the 14 data sets). Participants' responses were coded by two independent coders, whose agreement level was 85%. All discrepancies were resolved via discussion.

Table 2 presents a summary of these results. An overwhelming majority of the responses were in reference to the data and not to theoretical issues such as properties of the ball or robot/athlete. Many participants mentioned the specific data characteristics that were manipulated, including sample size (e.g., "They only tested it two times so they can't really be sure"), between-group variability characteristics such as reversed pairs ("All but once A went farther than B") or no reversed pairs ("A went farther than B every time"), and within-group variability characteristics such as variability within the column ("All the numbers in A are close together").

Table 2

Experiment 1: Percentage of Participants at Each Age Who Mentioned Each Justification for Their Sureness

	Third grade	Sixth grade	College
Data responses			
Sample size**	10	39	100
Reversed pairs*	56	70	90
No reversed pairs**	8	14	62
Spread of data**	3	15	44
Overall trend in data	92	93	100
Single pair "trend"**	23	0	0
Magnitude of differences**	46	89	92
Magnitude of single pairs	5	2	0
Mechanism responses			
Ball property	15	20	18
Robot/athlete property	41	37	30
Environment	3	2	2

Note. Age differences: $*p < .05$. $**p < .01$.

In addition, other characteristics not manipulated were also mentioned. The most frequently mentioned data characteristic was a trend in the data (e.g., "Five out of six times A went farther"; "B went farther most of the time"). Some third graders (23%) explicitly referred to only one pair of the data set, effectively ignoring the remaining data in their justifications; we called this type of response a "single-pair trend." No sixth graders or college students justified their reasoning this way. Another data characteristic mentioned was the magnitude of differences between the two columns of data (e.g., "A went much farther than B"). In general, college students used a much wider range of responses than younger children, with nearly all of them mentioning sample size at least once. However, all participants, with the exception of 2 third graders, mentioned at least one data characteristic at some point during the study.

In addition to discussions of data, we also explored whether participants offered causal or mechanistic explanations as justifications for their conclusions (Table 2). We coded explanations for a mention of characteristics of the robot (e.g., "Maybe the robot was breaking down after it threw Ball A"), characteristics of the athlete (e.g., "Maybe Person A was having a good day"), characteristics of the ball (e.g., "Maybe Ball B was more aerodynamic"), and characteristics of the environment (e.g., "Maybe there was wind blowing when Ball A was being thrown"). Across all trials, about half of the participants mentioned at least one mechanistic explanation, with no age differences (51% of third graders, 56% of sixth graders, and 42% of college students mentioned such an explanation).

One area in which a cover story difference might be expected is in use of these mechanistic justifications. Indeed, use of these mechanistic justifications did vary considerably by condition: Sixty-two percent of participants in the athlete condition said that a property of the athlete was a reason for at least one outcome, whereas 10% of those in the robot condition suggested a property of the robot as a reason for an outcome at least one time, $\chi^2(1, N = 133) = 38.19, p < .001$. In contrast, 6% of participants in the athlete condition and 29% of participants in the robot condition suggested a property of the ball as a potential explanation for the outcome at least one time, $\chi^2(1, N = 133) = 12.16, p < .001$. Mentions of other environmental mechanisms such as wind only occurred three times, twice in the robot condition and once in the athlete condition.

Discussion

When sample size, between-group variability, and within-group variability were manipulated, we found that sample size and the between-group variability influenced participants' reasoning but that within-group variability had no clear effect. In addition, older participants were able to make more accurate distinctions between data sets, indicating better knowledge of data characteristics individually and in concert. Children were also able to talk about data characteristics as early as in the third grade, demonstrating an early recognition of the importance of these concepts, but there were significant age-related increases in the number of data characteristics described in their explanations.

Although prior research indicates sensitivity to the law of large numbers at as early as age 7 (e.g., Klaczynski & Aneja, 2002), only college students indicated a clear appreciation of the law of large numbers by increased confidence ratings with increased sample size. Sixth graders showed a mixed pattern, and a sizeable number of third graders were less sure about conclusions when there were more data points—though this result does suggest sensitivity to the number of data points presented. These students may still be looking for a single correct answer and find multiple data points to be more confusing than informative.

In addition, there is evidence that in all three age groups, children pay attention to between-group variation in the data, one of the more complicated statistical concepts. Between-group variability in data is clearly salient to children even when the data are not couched in a strong theoretical context. Though this concept is relatively difficult in formal statistics, it may be implicitly provided by the presentation format of the data itself. For example, when scanning numbers presented in lists, when all numbers are visible simultaneously, and recall is not being tested, children may encode information about variability while encoding the values themselves. Thus, with age-related increases in processing capacity and speed as well as more optimal strategy use (e.g., Gathercole, Pickering, Ambridge, & Wearing, 2004; Kail, 2007), participants showed improvement in their ability to use information about sample size and between-group variability and to use the characteristics together in the form of an intuitive *t* test.

Participants did not seem to respond to changes in within-group variability, our manipulation of the standard deviation relative to the mean, though college students showed a small trend toward being more sure in cases with greater variability. It is possible that this characteristic was simply not salient or believed to be important and thus did not influence most responses. It is also possible that the lack of effect for children, and small reverse effect for college students, occurred because variability was confounded with data magnitude, such that the data with low variability relative to the mean consisted entirely of three-digit numbers, whereas the data with high variability relative to the mean consisted entirely of two-digit numbers. This confounding may have led to college participants simply rating themselves as more confident when reasoning about two-digit numbers instead of the more challenging three-digit numbers. In addition, with small sample sizes, the spread of the data may have been less noticeable.

One of our more intriguing findings was that participants appear to become increasingly adept with age at performing intuitive *t* tests on the data sets, that is, in using the data characteristics in concert. The lack of association of third graders' ratings with the *t*-test values of the data sets may be due to their consistently high confidence ratings. However, for the older participants, it indicates that even when participants were not systematically using the individual characteristics, they were able to use them together to draw conclusions, regardless of their level of explicit access to this information. The fact that the college students showed a small trend in being more confident with increased within-group variability while demonstrating strong evidence of drawing conclusions closely aligned with *t*-test results may indicate that for these data sets, the overall within-group variability was relatively small (even with our high-variability manipulation). Therefore, reasoning that focused on sample size and between-group variability may have been a reasonable way to draw conclusions about these data.

The participants not only used data characteristics in drawing conclusions but also justified their conclusions explicitly. In doing so, nearly every participant mentioned at least one data characteristic, though the college students referred to a wider range of characteristics and referred to these characteristics more frequently. The third graders appeared to be much less explicitly aware of concepts such as sample size and within-group variability, and the majority of their data-related comments were about trends in the data. Nonetheless, about half of the third graders referred to between-group variability and about half referred to the magnitude of differences between groups. The mention of these characteristics at all at such a young age indicates an early awareness that these features are important ones to consider in drawing conclusions from data.

In addition to the data features, even when we set up a situation with no clear mechanistic explanation, about half of the participants at each age brought their background knowledge to bear and mentioned potential mechanisms for the results that were not explicitly mentioned in the cover stories. Therefore, all students did not evaluate the data in a theory-neutral way. For some, predictions appealed to patterns in the previous data sets. For other students, predictions appealed to theoretical reasons for *why* such patterns were found.

One possible limitation of this study is that the presentation of data might have influenced reasoning by either providing too much information at once or guiding interpretation. Format of problem presentation has been shown to affect children's ability to solve math problems (e.g., Klein & Bisanz, 2000). If this amount of information exceeds processing limits, participants might use nonoptimal strategies for analysis. For example, instead of comparing the entire range of data at once, participants might draw a conclusion from the last set of numbers alone, ignoring the remaining data. In addition, for each trial in Experiment 1, participants were presented two data sets and asked to compare them. By presenting the data in this way, it is possible that participants would only compare *pairs* of data points instead of comparing the entire columns of data. To examine these issues, we conducted a second experiment.

Experiment 2

In the follow-up experiment, we explored how style of data presentation might influence children's and adults' conclusions. We made several specific changes to the methodology from Experiment 1. We changed the data presentation style so that the data were presented incrementally instead of simultaneously. This change in presentation allowed us to reduce the information processing burden and to compare the effect of presentation style on participants' processing of the data. Specifically, we wanted to explore whether the change from simultaneous to paired presentation would highlight different data characteristics (e.g., sample size) and obscure others (e.g., between-group variability). In addition, would a presentation format that prevents direct paired comparison lead to differences in reasoning about data characteristics? If understanding of data characteristics is robust, then the presentation format should have a minimal effect on using the characteristics to draw conclusions. However, if participants were only looking at subsets of the data, then we would expect the pairwise condition to lead to more confidence in evaluations derived from smaller samples. If participants were relying on individual pairwise comparisons as part of their reasoning, then the pairwise condition would likely lead to reasoning more clearly based on between-group variability than the column condition, in which the opportunities for such comparisons were limited. We also predicted that the two formats would lead to increased attention to the data characteristics, particularly to sample size, as the feature that most obviously changed between iterations.

We made other minor modifications in response to observations of participants in Experiment 1. We wanted to find out how likely participants were to want the engineers to test the balls again, an assessment of whether participants believed that they needed additional data to draw a conclusion. From the Experiment 1 cover story, one could argue that there is always a reason to be conservative in conclusions and state that there is not really evidence for a difference (a bias toward a Type II error rather than Type I error). Therefore, we modified the cover story to indicate more clearly that there are costs to being wrong in either assuming that balls go the same distance when they do not or assuming that they do not when in fact they do. This change was to reduce the possibility of participants suggesting simply producing and testing more balls without first considering the available data.

In addition, we changed some of the specific questions to be more explicit about exactly what we were looking for. In Experiment 1, we asked participants what the engineer had learned from testing, and nearly all participants gave answers about which ball went farther. If they did not, the experimenter probed for that answer directly. In Experiment 2, we changed the question to ask explicitly which ball went farther.

Finally, we added a practice problem that included three presentations of data and one reversed data pair to familiarize all participants with the nature of the task. The practice problem served to introduce participants to the notion that they would be seeing more data after the first trial and also that pair reversals in the data sometimes occur.

Method

Participants. Twenty-two third-grade students (mean age = 9.0 years, range = 8.2 – 10.6 years), 29 sixth-grade students (mean age = 11.9 years, range = 11.1 – 13.8 years), and 50 undergraduate students (mean age = 19.8 years, range = 17.8 – 23.6 years) participated in this study. None of these students participated in Experiment 1. The children were students in two elementary schools and two middle schools in the Northeast United States. The third-grade sample consisted of 54% White students, 21% Asian students, 18% Black students, and 9% Hispanic students. The sixth-grade sample consisted of 56% White students and 44% Black students. The third- and sixth-grade students were from different regions in the same metropolitan area than those who participated in Experiment 1. The college student sample consisted of 62% White students and 38% Asian students.

Procedure. Because there were no differences in the main conclusions drawn based on cover story, all participants in Experiment 2 were shown the robot cover story used in Experiment 1, with following paragraph added:

> It's very important that the engineers can find out whether the balls are the same or different. Only if the balls are the same and go the same distance can the factory sell them to make money. If they aren't the same then the engineers need to remake the balls, which is expensive and time-consuming. So the engineers need your help in looking at the results and deciding if they can be sure whether the balls are the same or different.

Participants were presented with three data sets, each with a different ball type, in one of two presentation formats. The three data sets were identical to those used in Experiment 1, and each included six pairs of data. One set had no reversed pair, one had one reversed pair (the third data pair was greater in Column B than in Column A), and one had two reversed pairs (the second and fifth data pairs were greater in Column A than in Column B). The order of presentation was counterbalanced using a Latin Square design, such that one third of the participants in each age group saw each data set first. All the data used in this study were from the high-variability (two-digit) condition from Experiment 1, as we found no clear effect of within-group variability on reasoning.

In the pairwise condition, participants saw data presented in two columns. First, they were shown one pair of data points, then two pairs, then four pairs, and then six pairs. After each presentation of data, participants were asked if there was a difference between the two balls, how sure they were of whether there was a difference and why, and whether they thought that the engineers should test the balls again. Examples of this condition are shown in Table 3.

Table 3
Example of Data Sets in Experiment 2

Examples of presentation formats shown to participants in the pairwise condition

Basketball A	Basketball B
74 ft	56 ft

Basketball A	Basketball B
74 ft	56 ft
83 ft	65 ft

Examples of presentation formats shown to participants in the column condition

Tennis Ball A	Tennis Ball B
49 ft	64 ft
40 ft	
39 ft	
51 ft	
50 ft	
38 ft	

Tennis Ball A	Tennis Ball B
49 ft	64 ft
40 ft	52 ft
39 ft	
51 ft	
50 ft	
38 ft	

In the column condition, participants saw six data points in one column and one in the other column. They were asked the same questions as in the pairwise condition and were then presented with additional data points in the second data column (one, two, four, and six data points at a time). This condition was included to see if reasoning changes when pairwise comparisons are less salient. Examples of this format are shown in Table 3. Questions asked in both formats were identical, with no explicit mention of the format in the questions.

Results

Judgments of whether there was a difference between the data sets. As in Experiment 1, responses—yes–no and sureness level—were combined into a single 7-point ordinal variable. Because there was no direct assessment of whether participants believed that the ball in Column A or Column B went farther, there was no accuracy measure. Participants stated only whether they thought that there was a difference between the two variables.

To examine the effect of sample size alone, we examined the data set in which reversed pairs were not included. Thus, we compared judgments of whether there was a difference between data sets when participants saw one, two, four, or six pairs of data or one column with six data points and a second with one, two, four, or six data points. These data points were all presented in the same scenario, and data points in one column were always larger than those in the other column. We found that sample size influenced participants' assessments of differences between the data sets. Age and condition were between-subjects variables, and sample size was a within-subjects variable. A 3 (age: third grade, sixth grade, or college) × 2 (condition: pairwise vs. column) × 4 (sample size: 1, 2, 4, or 6) mixed-model ANOVA was performed. We found no significant effect of age, $F(2, 95) = 1.73, p > .1$; no effect of condition, $F(1, 95) = 1.14, p > .1$; and a significant effect of sample size, $F(3, 93) = 4.52, p = .005$, partial $\eta^2 = .13$. There was also an Age × Sample Size interaction, $F(6, 186) = 3.87, p = .001$, partial $\eta^2 = .011$. Simple effects analysis to understand the nature of the interaction indicate that college students demonstrate a large, significant increase in sureness with increasing sample size in the pairwise condition, $F(3, 21) = 7.40, p = .001$, partial $\eta^2 = .51$, and in the column condition, $F(3, 23) = 17.37, p < .001$, partial $\eta^2 = .53$, but that third and sixth graders do not ($Fs < 1.0$). In addition, there was a significant Sample Size × Condition interaction, such that the paired condition leads to a linear trend of increasing sureness ratings with increased sample size, whereas the column condition does not, $F(3, 93) = 4.97, p = .003$, partial $\eta^2 = .14$. See Figure 3 for means for each age and sample size, by condition.

Between-group variability also influenced assessments of differences between data sets. The ratings of whether there was a difference between groups on the sixth trial (when all data had been presented) were compared across stories in a mixed-model ANOVA. Each participant saw one story with no reversed pair, one with one reversed data pair, and one with two reversed data pairs. A 3 (age: third grade, sixth grade, or college) × 2 (condition: pairwise vs. column) × 3 (between-group variability: zero, one, or two reversed data pairs) ANOVA was performed. We found no effect of age, $F(2, 95) = 0.74, p > .1$; an effect of condition, $F(2, 95) = 5.59, p = .020$, partial $\eta^2 = .06$; and an effect of between-group variability, $F(2, 94) = 12.60, p < .001$, partial $\eta^2 = .21$. On average, there were higher ratings of a difference in the pairwise condition and higher ratings with less between-group variability (i.e., with fewer reversed pairs). There was also a significant Age × Between-Group Variability interaction, $F(4, 188) = 3.87, p = .005$, partial $\eta^2 = .08$. Examining the Age × Variability interaction, only the college students reduced their sureness ratings considerably when there was more between-group variation, in both the pairwise condition, $F(2, 22) = 18.94$,

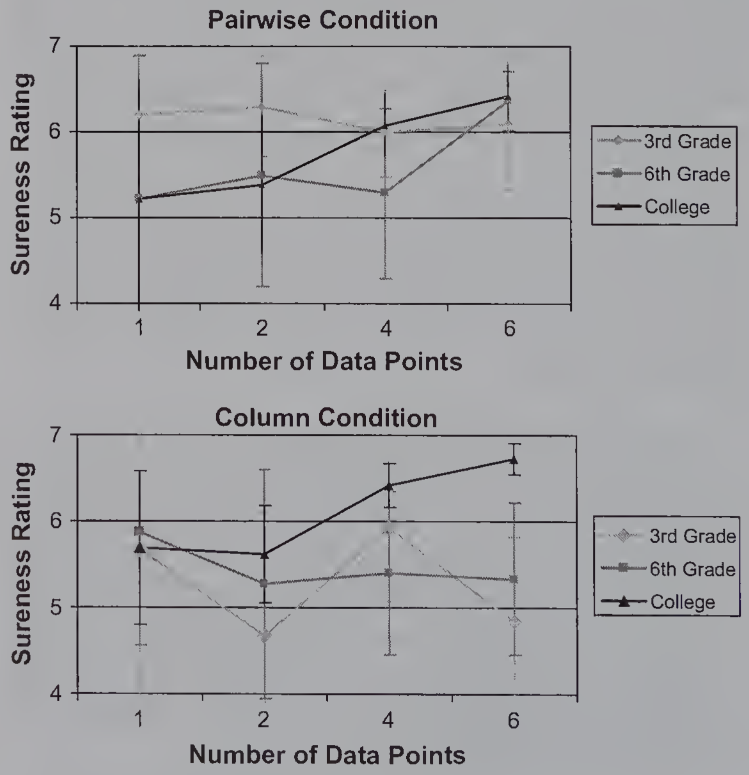

Figure 3. Experiment 2: Participants' sureness ratings at each grade with one, two, four, and six pairs of data but no reversed data pairs (by presentation format).
Note. Error bars represent standard error of measurement.

$p < .001$, partial $\eta^2 = .63$, and the column condition, $F(2, 24) = 20.61$, $p < .001$, partial $\eta^2 = .63$. There was a trend toward an interaction between age and condition, such that college students were more sure in the column condition, but third and sixth graders were more sure in the pairwise condition, $F(2, 95) = 2.37$, $p = .099$, partial $\eta^2 = .05$. The mean sureness ratings are presented in Figure 4 and indicate a clear pattern of decreased sureness ratings with increased variability in college students across both conditions.

As in Experiment 1, we calculated t tests for each set of data participants saw. In the pairwise condition, the t values ranged from 0 to 3.98. For this condition, we again found evidence of a strong association in college students between average sureness ratings and t statistics ($r = .924$, $p < .001$). Third graders exhibited a similar pattern ($r = .685$, $p = .042$). Sixth graders did not demonstrate a clear association ($r = .484$, $p = .177$). In the column condition, a different pattern emerged. These t values also ranged from 0 to 3.98, but only the college students showed any evidence of using this information systematically. College students' confidence in the difference between groups was very closely matched to actual t statistics ($r = .906$, $p = .001$). In contrast, third and sixth graders' ratings showed no evidence of a positive association between confidence and t statistics (third grade: $r = -.085$, $p > .5$; sixth grade: $r = .035$, $p > .5$).

Reasons offered. To classify explanations for reasoning, we began with the same codes as in Experiment 1. Two coders independently coded each set of explanations. The overall agreement level was 86.3%, and all discrepancies were resolved through discussion.

The pattern of explanations offered was similar to that in Experiment 1, with large grade effects. However, there were some key differences between the patterns of responses offered in Experiments 1 and 2. The frequencies of participants mentioning each explanation are summarized in Tables 4 and 5. The incremental data presentation led to more frequent mentions of data characteristics such as sample size (e.g., "The engineer should test again to get more data"; "Don't need to test again because we already have a lot of data"), suggesting that this format increased the salience of this characteristic. In Experiment 1, only 10% of third graders and 27% of sixth graders mentioned sample size. However, when directly comparing data sets with increasing data, 40% of third graders and 71% of sixth graders mentioned sample size in the pairwise condition, whereas 33% and 47%, respectively, did so in the column condition. Nearly all college students mentioned sample size. In discussing variability, mention of reversals or lack thereof was more common in the pairwise condition across all age groups. Mention of spread was similarly uncommon for third and sixth graders in the column condition as in Experiment 1 (8% and 13% as compared to 3% and 15%, respectively), and not a single third or sixth grader referred to spread in the pairwise condition.

Participants were asked to reason about all the data available in each scenario. However, as noted earlier, we found some participants explicitly stating that they only were referring to a single pair of data points in drawing conclusions. In Experiment 1, only 23% of third graders and 1 sixth grader ever clearly referred to a subset of the data in justifying answers. In

contrast, the incremental presentation formats in Experiment 2 led many more participants to reason this way. As shown in Tables 4 and 5, many participants in all age groups referred to a pattern or trend in a single pair of data points or to the magnitude of the difference between the two numbers of a single pair in justifying their conclusions (e.g., after seeing the final two numbers presented in the column condition, referring to only these two numbers: "52 is far away from 40"; similar patterns occurred after seeing the last pair in the pairwise condition). In fact, the only significant age difference in Experiment 2 on these issues was in the pairwise condition, where 80% of third graders, 43% of sixth graders, and 13% of college students referred to a "pattern" or "trend" based on a single pair of data to justify their responses, $\chi^2(2, N = 48) = 14.54, p < .001$.

We also expanded the codes used in Experiment 1 to include more codes for data-based responses. In the column condition, it was common for participants to justify their request for more data with a reference to the fact that the columns were unequal; thus, it was common for participants to say that they would like more data in Column B because there was currently not as much data as in Column A (e.g., "There's four more numbers on A and there still needs to be four more on B so it will be even," "You need even amounts of data"). Therefore, we noted whenever participants referred to unequal sample sizes. In addition, because we asked participants to assess whether they wanted more data, many participants used the data to make inferences about whether more data were needed. We added the code of inference to account for answers such as "It's pretty clear that they're different" and "More data will confirm it one way or another."

In addition to discussions of data, we also explored whether participants offered causal mechanistic explanations as justifications for their conclusions. As in Experiment 1, we coded explanations for a mention of characteristics of the robot, characteristics of the ball, and characteristics of the environment. Overall, a little more than one third of the participants mentioned at least one mechanistic explanation (e.g., "Because while the robot threw the first two balls, he may have lost some power"; "There might be damage or air leakage in the ball"), with no significant age differences (36% of third graders, 45% of sixth graders, and 34% of college students mentioned such an explanation).

Testing again. In Experiment 2, participants were asked if they thought the engineers should test the balls again. If they said yes, they were asked whether the engineers should test Ball A, Ball B, or both. With only one data pair, participants asked for more data 93.4% of the time; with two data pairs, participants asked for more data 90.1% of the time; with four data pairs, participants asked for more data 71.6% of the time; and with six data pairs, participants asked for data 40.9% of the time. The grade breakdown showed an interesting pattern after all six data pairs were presented. Third graders wanted to test for more data about 60% of the time across between-group variability levels (zero, one, or two overlaps). Sixth graders wanted to test for more data about 30% of the time across levels. College students, however, were most likely to differentiate among the data sets. Thus, although only 14% of the college students asked for more data when there was little between-group variability, 40% asked for more data when there was one overlapping pair and 56% asked for more data when there were two overlapping pairs. See Figure 5 for details.

Discussion

Experiment 2 was conducted to determine if the relative salience of various data characteristics could be manipulated by varying presentation format. The results suggest that presentation did not change the pattern of explicit reasoning shown in Experiment 1 for college students. The majority of college students clearly changed their ratings systematically with sample size. There were no differences in ratings of sample size based on whether the data were presented pairwise or in columns, indicating that the processing of each format was comparable for sample

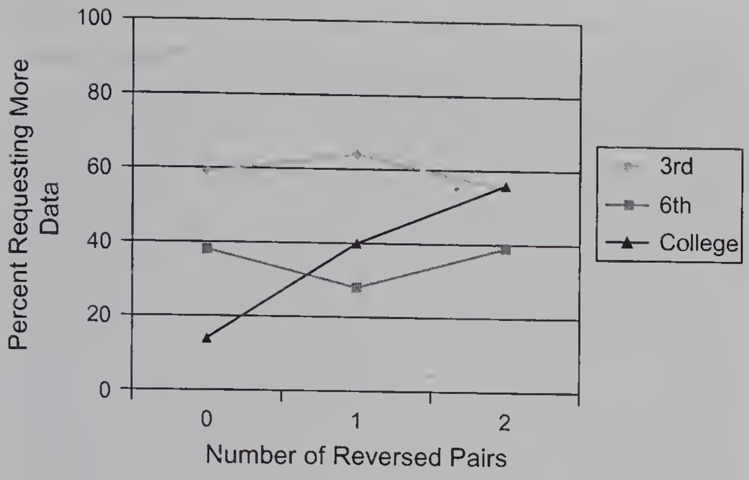

Figure 5. Experiment 2: Percentage of participants who requested further testing after six trials, based on between-group variability. *Note.* The data are broken down by age.

size ratings. However, third and sixth graders did not systematically use sample size when viewing data in these formats. This finding suggests that presenting data in this incremental format may in fact have made it somewhat more difficult for children to systematically use sample size when data sets they reasoned about were being updated.

However, the patterns of explicitly discussing sample size differed from Experiment 1. In Experiment 2, far more participants in the third and sixth grades talked about sample size as affecting their judgment. The presentation format increased the salience of this characteristic enough for many children to notice that sample size might play an important role. At the same time, incremental presentation of data led to more frequent references to trends in single pairs of data or subsets of the data instead of the whole pattern, though this trend was more pronounced for the younger participants. Because the task involved adding only one or two data points with each new trial, it is not surprising that this feature encouraged more participants to focus solely on a subset of the data rather than the whole, particularly in the pairwise condition.

Assessments of variability were also affected by data presentation format. College students demonstrated clear patterns of decreased sureness when there was more variability in the data, whereas the responses of younger participants were not as systematic. In addition, the format changes led to some differences in the explicit discussion of variability-related issues. In particular, participants appeared to be more likely to mention a lack of reversed pairs in the paired condition than in the column condition or in Experiment 1. Mention of spread of the data did not vary significantly by age, but mention of reversed pairs (or lack thereof) generally did. These findings suggest that children have a nascent understanding of variability but one that is not yet fully formed and applied equally across contexts.

General Discussion

The results of our study demonstrate that (a) children and adults attended to sample size and between-group variability when drawing conclusions from data; (b) there were significant age-related increases in the detection, use, and explicit awareness of individual data characteristics; and (c) the data presentation format affected the use of these characteristics. This research is the first to specifically examine the use of data characteristics outside knowledge-rich contexts and the ways these characteristics affect reasoning about data.

The framing in Experiment 1 allowed us to present two conditions (athlete, robot) that provided two different sources of error variance (e.g., human variation and robot variation, with the expectation that robots were likely to be perceived as less variable than humans). Although there were more mechanism-based explanations in the athlete condition than in the robot condition, there were few differences in how the data characteristics of sample size and variability were interpreted, suggesting that these characteristics were a source of information separate from domain knowledge. The fact that nearly every participant explicitly mentioned at least one data characteristic in justifying conclusions indicates an awareness of the importance of the numerical values. At the same time, Experiment 2 demonstrated that incremental data presentation led to more explicit reasoning about different data characteristics. These results suggest that participants may have difficulty reassessing sets of data with incremental additions to the data, even as these incremental additions make awareness of sample size more explicit. This pattern may indicate that initial values are disproportionately weighted relative to later values, though additional research is needed to evaluate this possibility. The most salient difference between presentation formats in Experiment 2 was in reasoning about between-group variability. In the column condition, participants still tended to use the characteristic but were slightly less sure of their conclusions, suggesting that the break from a focus on pairs often made them reason about the data set differently. However, when participants failed to consider the whole data set, they most often appear to have looked only at the most recently presented data and commented on a direct comparison on only this subset of the data.

The results demonstrate that children's data evaluations can be influenced by the characteristics of the data when comparing sets of data. But through what processes are reasoners making these comparisons? Though we did not specifically test this model, one possibility is that a mechanism for magnitude comparison and an explicit evaluation process may work in concert to produce the data interpretation described previously. Case and Okamoto (1996) provided evidence for a developmental model in which implicit processing mechanisms provide the foundation for children's learning in various domains such as number (i.e., central conceptual structures). Initially, development is highly constrained by processing limits that in turn constrain the number of dimensions a child can process, but as space and knowledge increase, children can attend to (and simultaneously process) multiple dimensions. Knowledge becomes increasingly available for explicit processing and can be extended to other areas (e.g., knowledge of living things). This model is one of many that suggest implicit processing mechanisms working in concert with gradually developing, explicit processes to account for developmental change within complex domains (e.g., Feigenson et al., 2004).

Our participants may have compared sets using approximate means and variances derived from the data. Though there is no definitive account of numerical estimation, one well-documented explanation suggests that number is represented by analog magnitudes that contain a proportion of error (as opposed to exact quantities; Gallistel & Gelman, 2000). There is evidence that estimating ability develops slowly and is difficult for many children and even adults (for discussion, see Siegler & Booth, 2005). Further evidence from recent research with adults suggests that estimating magnitude may be a general-purpose mechanism, showing similar patterns across varied information sources (Barth, Kanwisher, & Spelke, 2003). Although these studies presented data sets in a one-time comparison (not a series of data points to be combined later), our results suggest that the same representational mechanism used to represent and compare single quantities may represent and compare mean values. Obrecht, Chapman, and Gelman (2007) provided adults with a series of product ratings and found that participants were more confident in differences as mean differences increased and variance decreased, as in a *t* test.

If the process of mean computation is relatively automatic, then differentiating individual dimensions may require the acquisition of strategies that allow their identification and representation. Processing capacity (e.g., space, speed) likely plays a large role in the age-related performance differences (Gathercole et al., 2004; Kail, 2007). The transformation from presentation format (e.g., a set of values) into a different representational format (e.g., rough mean with error variance) requires sufficient space to implement these operations (Halford et al., 2007). In fact, this may be why children attended to sample size with simultaneous presentation (as in Experiment 1) but not with incremental presentation (as in Experiment 2). Research on processing capacity (e.g., Gathercole et al., 2004) indicates significant differences in working memory capacity between third and sixth graders and may help explain the age-related differences in attending to multiple data dimensions.

In addition, domain knowledge is likely necessary to identify individual data characteristics. Domain knowledge provides information about which dimensions may be associated with differences in behavior or performance. For example, if a professional golfer drives only 100 yards, most golf fans would ascribe this outcome to factors other than ability (e.g., wind, losing balance, losing concentration), whereas the same drive for a novice golfer might be ascribed to ability. In the present experiments, the domain knowledge was limited and was therefore only explicitly used some of the time in justifying conclusions. Setting the same data in a context in which participants have very strong prior theories may have led to different results and much greater reliance on this background knowledge (e.g., if we told participants Golfer A was a professional golfer and Golfer B was a complete beginner).

Related to domain knowledge is knowledge about using data themselves, particularly in understanding the relationship between a sample and a population. Increasing sample size increases the approximation to the population under study. Younger children in the present experiments did not appear to treat data as samples, as there was little effect of sample size. Paradoxically, third graders were often more certain with a single observation than with multiple observations. Perhaps, a source of young children's difficulty is an assumption that one observation is indicative of a population.

The results of this study suggest a prominent role for data in children's reasoning. Absent strong background knowledge, children make use of data as a source of information. Future research should more closely examine the influence of processing factors such as capacity and speed, in addition to varied representations. Future research should also examine how children's use of data (and data characteristics) might be useful for acquiring knowledge in novel domains.

Conclusions

In sum, these findings demonstrate that children and adults attend to the number and variability of observations when interpreting data. The results also demonstrate that the use of these characteristics improves with age and becomes more explicitly accessible. Response patterns are consistent with an intuitive *t* test, in which reasoners represent and compare an approximate mean that includes information on the variability of observations. With experience, children better identify the individual dimensions (e.g., variability), attend to finer distinctions of these dimensions, and increase their explicit access to this information. Although children's background knowledge is an important factor in interpreting data, our results indicate that the characteristics of the data themselves play a role in how children make sense of observations.

Intergenerational Transmission of Social Anxiety: The Role of Social Referencing Processes in Infancy

Lynne Murray, Marc de Rosnay, Joanna Pearson, Caroline Bergeron, Elizabeth Schofield, Melanie Royal-Lawson, and Peter J. Cooper
University of Reading

Responses to an unfamiliar adult were examined in infants of mothers with social phobia ($N = 79$) and infants of nonanxious comparison mothers ($N = 77$) at 10 and 14 months in a social referencing paradigm. On each occasion, a female stranger first interacted with the mother and then approached and interacted with the infant. Over time, infants of mothers with social phobia showed increasing avoidance of the stranger, particularly when they were behaviorally inhibited. In boys, maternal social phobia was associated with increasing fearful responses. Infant avoidance was predicted by expressed maternal anxiety and low levels of encouragement to interact with the stranger. The findings are discussed in relation to theories concerning the intergenerational transmission of social anxiety.

Social phobia is one of the most common of the anxiety disorders, with a lifetime prevalence of 7%–13% (Furmark, 2002). In its generalized form, social phobia is characterized by a marked fear and avoidance of most novel social situations where the individual may be subject to scrutiny by others (e.g., participating in small groups, initiating or maintaining conversations), and by the fear that, in such situations, the individual will behave in a foolish or embarrassing manner (*Diagnostic and Statistical Manual of Mental Disorders* [4th ed.; *DSM–IV*], American Psychiatric Association, 1994). The disorder is severe and disabling and, without treatment, it tends to run a chronic course (Solyom, Ledwidge, & Solyom, 1986). Social phobia aggregates in families, with children of affected parents being themselves at risk (Lieb et al., 2000; Mancini, Van Ameringen, Szatmari, Fugere, & Boyle, 1996). A number of processes are likely to be involved in the intergenerational transmission of social anxiety. Genetic mechanisms are likely to contribute to risk (Eley, 2001), with twin studies showing significant, albeit moderate, genetic influence (Kendler, Karkowski, & Prescott, 1999; Nelson et al., 2000). Some of the variance in social anxiety is accounted for by genetic factors that are unique to this kind of anxiety (Kendler, Myers, Prescott, & Neale, 2001), but it appears that most of the genetic influence involves risk for emotional problems in general, including anxiousness and depression (Andrews, 1996; Eley, 1999). Relatedly, the role of temperament has been considered important in the development of social anxiety, and, in particular, it has been suggested that the temperamental constellation of behavioral inhibition (Kagan, Reznick, & Snidman, 1987) may represent a direct developmental precursor of the disorder (Stemberger, Turner, Beidel, & Calhoun, 1995). In favor of such a link is the finding that behavioral inhibition, usually measured from late infancy, raises the risk of anxiety disorder, especially the social type (Biederman, Rosenbaum, Bolduc-Murphy, & Faraone, 1993; Hirshfeld, Rosenbaum, Biederman, & Bolduc, 1992; Turner, Beidel, & Wolff, 1996).

The importance of environmental influences has also been stressed (Rapee & Spence, 2004). Among these, parenting practices have been emphasized, although direct evidence of their influence is limited (McLeod, Wood, & Weisz, 2007; Wood, McLeod, Sigman, Hwang, & Chu, 2003). This is particularly so with regard to mother–infant interactions, where samples have been small and have often included a variety of disorders. Furthermore, although previous research has consistently highlighted a number

of parenting styles as posing a risk (e.g., overcontrolling/overprotective and unaffectionate parenting and the modeling of fearful behavior), concerns have been expressed about the robustness of these associations. In particular, it has been argued that insufficient account has been taken of the direction of effects, that there has been a lack of specificity in the conceptualization of the parenting practices concerned, and that assessment frames have been too general to identify the characteristics of specific disorders (Wood et al., 2003). There is, therefore, a need for longitudinal studies of parents with social phobia, in which systematic observations of parenting are made of adequate samples in contexts designed to elucidate the core clinical difficulties associated with the disorder.

A notable feature of social phobia, particularly of the generalized form, is its early onset. This suggests that in seeking to understand the development of social phobia, it will be valuable to study processes occurring early on, including those in infancy. Two features of the normal infant developmental process can be hypothesized to have a particular bearing on the development of social anxiety. First, at around 7–9 months of age, infants normally begin to show wariness in relation to unfamiliar adults, with increasingly negative reactions occurring over the rest of the 1st year (Sroufe, 1977). The second relevant process is *social referencing* or social information gathering; this concerns the way in which infants acquire information from other people concerning the emotional significance of aspects of their environment and how particular patterns of infant responsiveness to the environment may be engendered and maintained. Thus, from around 10 months, infants begin to seek information from their mother, or other relevant adult, concerning the adult's emotional response to, and appraisal of, a referent (e.g., an unfamiliar object or unfamiliar person); infants are then likely to modify their own behavior in line with that response. A large volume of research has accumulated concerning the conditions under which social referencing processes are likely to occur (Feinman, Roberts, Hsieh, Sawyer, & Swanson, 1992). Although there has been some variability in results, a number of findings have emerged of particular relevance to the question of the intergenerational transmission of anxiety. Thus, the impact of the adult's response may be especially marked in situations where the infant already experiences some uncertainty about the referent (Gunnar & Stone, 1984), and negative adult responses, including fearful responses, may be experienced by the infant as particularly salient (Hornik, Risenhoover, & Gunnar, 1987; Moses, Baldwin, Rosicky, & Tidball, 2001). Furthermore, at least with regard to infant responses to unfamiliar persons, the mother may be a privileged source of information (Feiring, Lewis, & Starr, 1984).

Taken together, these findings suggest an important route whereby social anxiety may be transmitted from mother to infant. Thus, at a time when the normative development of stranger fear emerges, the infant's vigilance concerning their caretaker's responses to other people is likely to result in any socially anxious behavior on the part of the mother leading the infant to adopt similar patterns of interpersonal responsiveness.

A number of processes may be involved in the transmission of socially anxious behavior from mother to infant. The first concerns the infant's or child's *observation* of their parent's response to the environment, sometimes referred to in the social referencing literature as an *indirect effect* (e.g., Feinman & Lewis, 1983) and the ensuing *modeling* by the child of the adult's behavior and affect (e.g., Gerull & Rapee, 2002; Muris, Steerneman, Merckelbach, & Meesters, 1996). A different set of processes concerns the parent's *direct* communication to the child about the referent and the ensuing management of the child's response. For example, the adult may encourage the child's engagement with the referent, thereby promoting child mastery and autonomy (e.g., Hornik & Gunnar, 1988). Conversely, they may attempt to limit the child's exposure to the referent (e.g., by taking over control of the object or the interaction with the other person themselves), thereby reinforcing and maintaining any initial child apprehension (e.g., Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Rubin, Hastings, Stewart, Henderson, & Chen, 1997).

Here, we report on the development of socially anxious behavior in infants of mothers with social phobia and infants of nonanxious comparison mothers in a prospective, longitudinal study using a social referencing paradigm in which the mother was required to interact with an unfamiliar adult, a situation that was likely to elucidate the expression of any maternal social anxiety. Thus, a stranger first conversed with the mother in full view of infant, thereby allowing the infant to observe any signs of maternal anxiety and the nature of the mother–stranger interaction. Then, the mother was invited to introduce the stranger to the infant, whereupon the stranger approached and interacted with the infant. This second episode provided the opportunity for the infant to observe continuing maternal anxiety and also elucidated maternal management strategies potentially relevant to the transmission of anxiety. A particular merit of the social referencing paradigm is that it is analogous to many real-world social encounters in which the infant has the opportunity of observing parental management of ambiguous situations before making their own response.

We conducted an initial assessment at 10 months, when infants already show wariness or fear of strangers, but social-information-gathering strategies are not yet established, although they are nascent, and we made a second assessment at 14 months. A notable feature of social referencing research findings is that effects have generally been of only moderate magnitude; this is partly a function of the considerable individual differences in infant behavior. In view of this, we focused on the development of socially anxious behavior *within* individual infants from 10 to 14 months. We hypothesized that at a time when infants are both experiencing fearful responses to strangers and are monitoring the behavior of their caregivers as part of the process of social referencing, those whose mothers had social phobia would, compared to infants of comparison mothers, become progressively more fearful and avoidant of contact with the stranger over the period between the two observations.

Although offspring of individuals with social phobia are, in general, at raised risk for the disorder themselves, only a proportion are affected (e.g., in the study of Mancini et al., 1996, it was 25%), and it is important to investigate factors that may render some offspring more vulnerable than others. Thus, in addition to examining the overall effects of maternal social phobia on the development of infant socially anxious responses to a stranger, we investigated the effects of two further potentially important influences: first, the infant temperamental constellation of behavioral inhibition and, second, specific aspects of maternal behavior that have been linked to the occurrence of child anxiety (Wood et al., 2003).

Infant behavioral inhibition, which has commonly been measured at 14 months or later (e.g., Calkins, Fox, & Marshall, 1996; Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Kagan et al., 1987), refers to a general tendency to be fearful and withdrawn in the face of novelty. In the present study, where we were primarily concerned to examine the change in infant *social* fear and avoidance from 10 to 14 months, the inclusion in the definition of behavioral inhibition of infant responses to social novelty (i.e., to unfamiliar people) as a predictor variable would have entailed a fundamental confound with our outcome measure. We therefore restricted our assessment of infant behavioral inhibition to nonsocial contexts that have been widely used in the literature (see the Procedure section). We predicted that infants who were identified as inhibited in nonsocial contexts would show a greater increase in social fear and, in particular, avoidance in their interactions with the stranger over the critical developmental period between 10 months (when social information gathering is nascent) and 14 months (when infants are clearly able to engage in social referencing). We further hypothesized such infants would be more vulnerable to the effects of maternal social phobia than infants who were not inhibited; hence, we expected that behaviorally inhibited infants of mothers with social phobia to become more fearful and avoidant with the stranger over this time period.

With regard to the effects of maternal behavior on the infant's response to the stranger, we expected mothers with social phobia, in general, to express high levels of anxiety with the stranger, to be less encouraging of their infant's interaction with the stranger, and to be overcontrolling or intrusive when attempting to manage their infant's interaction with the stranger. Given that it is exactly these parenting behaviors that have consistently been found to be associated with anxiety in older children (Gruener, Muris, & Merckelbach, 1999; McLeod et al., 2007; Muris et al., 1996; Wood et al., 2003), we predicted that their occurrence would be associated with an increase in infant fear and avoidance of the stranger over the period from 10 to 14 months. Furthermore, we predicted that it would be by virtue of these features of the behavior of mothers with social phobia that their infants would develop increasingly negative responses to unfamiliar people; thus, we expected that once account was taken of these maternal behaviors, any effects of maternal social phobia on infant responses to the stranger would cease to be significant, that is, that such maternal behavior would mediate any effects of maternal social phobia on infant social responsiveness.

Finally, we addressed two subsidiary questions concerned with the issue of whether some infants may be more vulnerable to the effects of maternal social phobia than others. First, although effects of infant sex in the social referencing literature have traditionally been small and equivocal (Feinman et al., 1992), more recent evidence suggests that compared to boys, girls may modify their behavior more strongly when their mother expresses fear toward a referent (Blackford & Walden, 1998; Gerull & Rapee, 2002). We therefore took account of the infant's sex in the analyses. Second, because it is common in individuals with social phobia for there to be other concurrent anxiety disorders (Schneier, Johnson, Hornig, & Weissman, 1992), we conducted exploratory analyses to determine whether the presence of additional disorders affected the impact of maternal social phobia on infant development.

Method

Sample

Seventy-nine mothers with social phobia and 77 nonaffected comparison mothers, together with their infants, comprised the sample for the current study. They formed part of a larger sample, recruited from the Royal Berkshire Hospital in Reading, United Kingdom. Reading is a large town in the southeast of England, with a population (144,000) broadly reflecting the demographic characteristics of the country. Recruitment proceeded as follows: Four thousand mothers attending routine 20-week antenatal scan clinics at the hospital completed an eight-item screening questionnaire for social phobia. Three hundred sixty-six high-scoring women were recontacted; of these, 107 (29.2%) refused to participate in the study and 47 (12.8%) were found to be ineligible (e.g., because of moving away). The remaining 212 women were interviewed within 1 month to confirm diagnosis. Of these, 105 (49.5%) did not meet *DSM–IV* diagnostic criteria; 107 women were identified with social phobia of the generalized type (Stein et al., 1998) and were recruited. Twelve of these women subsequently became ineligible (e.g., due to premature delivery, infant death). A random sample of 164 women with low screening scores was also approached for participation in a comparison group: Thirty-two (19.4%) refused to take part and 9 (5.5%) were ineligible. The remaining 123 were interviewed to assess their mental state: Twenty-one were excluded as they had anxiety disorders other than social phobia and 7 mothers became ineligible; 1 woman was diagnosed with social phobia and was therefore recruited into the index group, bringing the final total in this group to 96. The remaining 94 women were recruited into the comparison group on the basis of having no current or past social phobia or any other anxiety disorder. The study sample was representative of those screened. Mean scores on the social phobia screening questionnaires for those who declined to participate did not differ significantly from those of women who were recruited and were, for high-scoring women, 23.05 ($SD = 4.05$) and 22.74 ($SD = 4.55$), respectively, $U = 5261.5$, $p = 0.31$. Similarly, for the low-scoring women, scores for those declining to participate and for those who were recruited into the comparison group were 9.75 ($SD = 2.27$) and 10.64 ($SD = 2.63$), respectively, $U = 1{,}311.5$, $p = 0.1$.

Of the 96 women with social phobia, 43 (45.7%) had no other anxiety disorder, 30 (31.9%) had comorbid generalized anxiety disorder, 21 (22.8%) also had a specific phobia, 8 (8.5%) had agoraphobia, 4 (4.3%) had panic disorder, and 3 (3.2%) had obsessive-compulsive disorder; in addition, 5 (5.2%) were depressed. One (1.1%) of the comparison group mothers was also depressed. The two study groups were similar in terms of demographic characteristics. Thus, for the comparison and social phobia groups, respectively, mean maternal ages were 31.2 ($SD = 4.2$) and 30.4 ($SD = 5.1$) years, and in each, the great majority of the mothers were Caucasian (94.7% and 100%) and were married or cohabiting (95.7% and 92.7%). Few were of low socioeconomic status (7.4% and 16.7%). Fifty percent of the comparison infants were boys, as were 39.6% of the social phobia group infants; infant birth weight was also comparable in comparison and social phobia groups ($Ms = 3{,}505$ g and 3,520 g, $SDs = 477$ and 411, respectively). At the 10 and 14 month assessments, because of infant illness or extreme distress at the start of testing, assessments could not always be conducted. The participants for whom data were available at both time points—79 (82.3%) of the social phobia group and 77 (81.9%) of the comparison group—did not differ from those without on maternal questionnaire responses or demographic characteristics (all $ps > .1$), and infant age at each assessment did not differ between groups ($Ms = 45.0$ weeks and 44.6 weeks, $SDs = 2.3$ and 2.2, respectively, for the first assessment and $Ms = 60.8$ weeks and 61.2 weeks, $SDs = 2.9$ and 3.8, respectively, for the second assessment, for comparison and social phobia groups, respectively).

Procedure

Mothers and their infants attended a university research unit at 10 and 14 months, when we conducted the assessment of infant social referencing and social anxiety; at 14 months, we also assessed infant behavioral inhibition. On each occasion, mothers completed rating scales concerning their current level of social anxiety. For the social referencing experiment, a researcher first described the procedure to the mother. Because we wished to observe any naturally occurring differences between mothers with social phobia and comparison mothers, unlike social referencing experiments in which mothers receive detailed instructions and training in how to behave, we asked the mothers to behave as they normally would. Mother and infant were then settled in an experimental room and were filmed via a one-way mirror. The infant was seated in a high chair with restraints, and the mother was seated 5 ft away from the infant. A female researcher, unfamiliar to mother and infant, entered the room, and, in the first phase of the experiment, she engaged the mother in conversation for a period of 2 min, asking her about the infant and her experience as a mother. In the second phase, the stranger informed the mother that she was going to approach the infant and asked the mother first to introduce her. The stranger then called to the infant and made a graded approach to the point where she stood close, looking at the infant directly; she stretched out her arms and touched the infant's arm. This approach phase lasted approximately 1 min. In the final phase, also lasting 1 min, the researcher unstrapped the infant from the chair, picked the infant up, and held him or her, positioning herself so that the infant and mother could see each other throughout. The stranger then talked to the infant in a friendly manner while watching the infant's face. The mother was free to interact with the stranger and the infant throughout.

For the assessment of behavioral inhibition, infants were observed in a paradigm in which latencies to approach and fearful or distressed behaviors toward novel objects and situations were assessed (Kagan et al., 1987). The assessment devised by Kagan et al. (1987), and used throughout the literature, involves exposure to both nonsocial and social (including stranger approach) stimuli. As already noted, in the present study because our outcome measure was the infant's response to an unfamiliar stranger and we wished to examine behavioral inhibition as a predictor or moderator of infant social anxiety, it would have been circular to use a behavioral inhibition index that included responses to social stimuli. Thus, to address the question of whether a general temperamental tendency to withdraw from novel and potentially threatening situations underlay any infant social avoidance, we used only the nonsocial elements of the assessment of behavioral inhibition. First, we recorded the infant's response to a mechanical dinosaur that moved and "roared"; the infant was seated on the carpet in the observation room and the dinosaur was placed approximately 3 ft away for a period of 3 min. Next, the infant was observed for 3 min in an unfamiliar playroom, with the mother present, where a collection of novel toys was available.

Measures: Maternal Mental State

(a) Screening questionnaire: An eight-item questionnaire derived from the Social Interaction and Anxiety Scale and the Social Phobia Scale (SIAS and SPS; Mattick & Clarke, 1998) was used. Items were included on the basis of their high factor loadings on these measures. Scores ranged from 8 to 37. A pilot of the screen showed a cutoff score of 17 to identify the top scoring 10% of respondents. (b) Diagnostic interview: Mothers were interviewed by trained psychologists and mental health clinicians with the Structured Clinical Interview for *DSM–IV* Axis 1 disorders (First, Spitzer, & Williams, 1995) to assess the presence of anxiety and depression. All interviews were subsequently discussed with a senior clinical team to confirm diagnosis and assignment to the two study groups. (c) Maternal social anxiety symptoms at 10 and 14 months: The full versions of the SPS and the SIAS were administered.

Measures: Maternal and Infant Behavior in the Social Anxiety Paradigm (10 and 14 Months)

On the basis of the literature on the parenting behaviors of mothers with anxiety disorders and that on infant social referencing, the following maternal and infant behaviors were scored.

Maternal behavior during the mother–stranger interaction. (a) Maternal anxiety: Signs of anxiety were rated on two 5-point scales: The first comprised ratings of facial expression (e.g., grimaces, biting lip, anxious/fearful expression) and bodily behaviors (e.g., wringing hands, tense posture) and the second, the quality of speech (e.g., nervous laughter, rushed and agitated, or else highly constrained, speech). Scores for the two scales were then summed. (b) Maternal engagement with the stranger: The extent of maternal talkativeness was rated on a 3-point scale; maternal avoidance of eye contact was similarly rated. The latter score was reversed and summed with the talkativeness score to give an overall measure of engagement.

Maternal behavior during the stranger–infant interaction. (a) Maternal anxiety: The same ratings were used as above. (b) Maternal encouragement: This rated the mother's positive encouragement of the infant's interaction with the stranger. Maternal nods and smiles, positive facial expressions, looks, and eyebrow flashes directed to the infant as the stranger approached and interacted with him or her were rated on a 3-point scale. (c) Maternal overcontrol/overprotection: This rated, on a 5-point scale, the extent to which the mother intervened in the stranger–infant interaction, for example, by interrupting and taking over the stranger's attempts to engage with the infant.

Infant behavior during the mother–stranger interaction. Infants varied in their emotional state at the start of the experiment. At 10 months, this appeared to be principally in response to being placed and restrained in the infant seat, although heightened wariness in response to the new surroundings was also possible. For these reasons, we took into account the extent of 10-month initial negativity, before the stranger's approach, when subsequently evaluating infant response to the stranger. Initial negative emotional tone was rated using a 5-point scale. This comprised ratings of facial and vocal expressions of distress, as well as bodily movements such as squirming and back arching. To ensure that the infant was able to obtain visual information about the mother's response to the stranger, whether the infant watched the mother was also scored as present or absent.

Infant behavior during the stranger–infant interaction. (a) Positive engagement: This was coded as present or absent and concerned positive behaviors such as smiling or laughing and clearly positive vocalizations directed to the stranger. (b) Infant fear: This was rated on a 5-point scale and included facial expressions of wariness (excluding avoidance) and fear and postural behaviors such as freezing. (c) Avoidance of stranger: Ratings were made on a 5-point scale and concerned active attempts to avoid contact, either through gaze avoidance or physically withdrawing or turning away. We examined infant avoidance of the stranger in two distinct periods during the infant–stranger interaction: the *approach* phase (during which the stranger approached the infant and made minimal physical contact) and the *pick-up* phase (during which the stranger unstrapped the infant and picked him or her up).

Maternal and infant behaviors during the mother–stranger interaction were scored in two equal time blocks of 1 min. During the infant–stranger interaction, there were four scoring blocks: three in the approach phase (each of 20 s) and one in the pick-up phase (1 min). This increased coding reliability and also meant that behavioral continuity within the interaction periods could be assessed.

Videotapes were scored by two researchers who were blind to both maternal group and the results of the assessment of infant behavioral inhibition. Twenty tapes selected at random were scored by both researchers to establish reliability. For continuous measures of maternal and infant behavior, Kappas ranged from .65 to .80. For the binary variables of infant positive engagement with the stranger and infant look to mother, Kappas were 0.79 and 1.00, respectively.

Infant behavioral inhibition in nonsocial settings. Infant behavioral inhibition was scored as present or absent in each of the four observation periods (one 3-min period for the playroom with unfamiliar toys and three 1-min periods for the dinosaur). For the playroom, where distress and fear were very rarely observed, an inhibited response was defined as the infant's maintaining close proximity to the mother and failing to approach the toys for at least 2 min of the whole 3-min period. For the dinosaur, an inhibited response was defined as the presence of fearful or distressed behavior, reflected in failure to approach the dinosaur, fretfulness and crying, scored in each 1-min period. We used both the continuous score of 0–4 (being the sum of the single playroom observation plus the three dinosaur observation scores) and a categorical measure of high behavioral inhibition (> 2 on the 0–4 point continuous score, reflecting the 25% most inhibited infants). Videotapes were scored by two trained researchers who were unaware of maternal group and of the results of the social referencing experiment. Twenty tapes were scored by both researchers to establish reliability. Mean Kappas for the continuous measures were 0.89, and for the categorical measure Kappa was 1.0.

Results

Continuing Maternal Social Anxiety Symptoms

There was considerable stability in mothers' experience of anxiety symptoms between the two assessments; rank order correlations being, for the SPS, .87, and for the SIAS, .91. Relatedly, the level of social anxiety experienced by the two study groups continued to differ; thus, the mean scores on the SPS for social phobia and comparison mothers at 10 months were 22.56 (*SD* = 13.90) and 5.59 (*SD* = 5.53), respectively ($U = 458.5, p < .001$), and at 14 months, 22.26 (*SD* = 14.09) and 5.48 (*SD* = 7.08), respectively ($U = 540.5, p < .001$). On the SIAS at 10 months, mean scores for the index and comparison groups were 39.70 (*SD* = 11.49) and 12.46 (*SD* = 7.21), respectively ($U = 105.5$, $p < .001$), and at 14 months, they were 39.38 (*SD* = 12.44) and 11.64 (*SD* = 8.89), respectively ($U = 150.5, p < .001$). The SPS and SIAS means for the social phobia mothers are comparable to those of clinic samples (Coelho, 2004).

Behavioral Inhibition

A similar proportion of index and comparison infants was classified as behaviorally inhibited: 18 (22.8%) and 15 (19.5%), respectively, $\chi^2(1) = 0.26$, *ns*; mean scores on the continuous measure for the two groups were 1.24 (*SD* = 1.30) and 1.08 (*SD* = 1.34), respectively, $t(154) = -.77$, *ns*.

Ratings of Maternal and Infant Behaviors in the Social Referencing Procedure

Examination of the frequencies and distributions of the infant and maternal behaviors at 10 months showed the occurrence of maternal overcontrol to be very infrequent (only 12 [7.7%] mothers); therefore, this variable was not considered further. With regard to infant behaviors, the measure of positive engagement with the stranger was significantly negatively correlated with that of fearfulness ($r = -.43, p < .01$); given the theoretical importance of fear of unfamiliar persons for this study, we retained this latter measure and excluded that of positive engagement from further analysis. The ratings of infant fear showed acceptably low levels of intercorrelation with those of avoidance (range = −.03 to .14, all *ns*). Notably, infant fear was highly consistent across the four scoring blocks of the infant–stranger interaction (Cronbach's $\alpha = .79$). By contrast, infant avoidance was far less stable (Cronbach's $\alpha = .37$), principally due to a marked escalation in avoidance when the stranger picked the infant up, thus confirming the need to treat behavior in this final pick-up phase as distinct from that during the stranger's approach. Inspection of distributions confirmed that it was appropriate to treat all continuous maternal and infant variables in their original, untransformed form.

Before investigating the change in infant behavior toward the stranger over time, and its determinants, we examined maternal and infant behavior in the two groups at 10 months, and the continuity in maternal behavior over time (see Table 1).

For maternal behavior at 10 months, those with social phobia showed significantly more anxiety than those in the comparison group, both during their own interaction with the stranger, $F(1, 154) = 4.16, p < .05$, and during the infant–stranger interaction, $F(1, 154) = 9.75, p < .01$. Index mothers were also significantly less engaged with the stranger than the comparison group, $F(1, 144) = 5.37, p < .05$, and they were somewhat less encouraging of infant interactions with the stranger, $F(1, 154) = 3.26, p = .07$. This

Table 1

Group Means (SDs) and Ranges for Maternal and Infant Behaviors at 10 and 14 Months

Note. BI = behavioral inhibition.

pattern of group differences was retained at 14 months, and the extent of change in maternal behavior over time did not differ between groups. In contrast to maternal behavior, infant behavior at 10 months in the social referencing paradigm did not differ between the index and the comparison groups, for avoidance during the stranger's approach, $F(1, 136) = 1.18$, *ns*; avoidance during the stranger pick-up $F(1, 142) \leq 1$, *ns*; or fearfulness, $F(1, 136) \leq 1$, *ns*.

Change in Infant Social Behavior With the Stranger

Initial data checking showed that there were eight statistical outliers (four comparison [5%] and four index [5%]) on the avoidance measures during the 10-month assessment (> 2.5 *SD* from the mean) who were excluded from the main analyses reported below. However, including these infants did not alter the overall pattern of findings (including significance). Means, standard deviations, and ranges for infant behaviors during the infant–stranger interaction are shown in Table 1. All infants looked at their mother at some point during the time when she interacted with the stranger and during the stranger–infant interaction.

To examine change within individual infants' behavior from 10 to 14 months (calculated following the analytic strategy outlined by Bock, 1985, p. 489, by subtracting the 10-month from the 14-month score), and the extent to which infant behavioral inhibition, maternal group (comparison vs. social phobia), and maternal behavior at 10 months accounted for this change, we adopted a two-stage approach. First, we examined the influence of infant behavioral inhibition, maternal group, and their interaction (Inhibition × Group) using hierarchical linear multiple regression analyses. All continuous variables were centered, and categorical variables were coded as dummy variables. For each analysis, infant sex and negative emotional tone at 10 months were entered at the first step (base model). At the second step (main effects model), behavioral inhibition and maternal group were entered. At the final step (full model), the interaction term, Behavioral Inhibition × Group, was entered. Table 2 shows the Pearson correlation coefficients between predictor and outcome variables. The results of the regression analyses are presented in Table 3. In keeping with the overarching conceptualization of behavioral inhibition (Calkins et al., 1996; Kagan et al., 1987), we present these analyses with behavioral inhibition classified as a binary variable. In fact, results were not materially altered when it was treated as a continuous measure.

For the second stage of our analyses, we examined further the interactions identified in the first stage and explored the possibility of additional interactions between predictor variables where appropriate. We also conducted *process analyses* to establish whether 10-month maternal behaviors mediated any significant relations between behavioral inhibition, group or Behavioral Inhibition × Group, and change in infant behavior with the stranger, using the four steps outlined by Baron and Kenny (1986) and Preacher and Hayes (2004). We focus on 10-month maternal behaviors because of the importance, within a developmental framework, of establishing a predictive association between maternal behavior and change in infant responses to the stranger. As a final check, however,

we also examined whether any potential effects of 10-month maternal behaviors were better accounted for by 14-month maternal behaviors.

Infant avoidance of the stranger in the approach phase. During the stranger approach, only the interaction term, Behavioral Inhibition × Group, significantly contributed to change in stranger approach avoidance from 10 to 14 months. This interaction is depicted in Figure 1a, which shows that behaviorally inhibited infants of mothers with social phobia (n = 18) had a greater increment in avoidance during the stranger approach than noninhibited infants of index mothers (n = 57; see right-hand side of Figure 1a); a post hoc t test of this mean difference (.41) was marginally significant (p = .05). By contrast, behaviorally inhibited infants of comparison mothers (n = 15) had the smallest increment in avoidance to the stranger during the approach phase; a post hoc t test of the mean difference (.47) between inhibited infants of index and comparison mothers approached significance ($p < .10$). No further interactions (e.g., Sex × Group) were significant. Exploratory analyses (e.g., see Table 2) indicated that maternal encouragement might mediate the effects of the interaction between infant behavioral inhibition and maternal social phobia on the change in the infant's avoidance of the stranger, that is, a *mediated moderation effect* (Baron & Kenny, 1986; Muller, Judd, & Yzerbyt, 2005). The first step of the mediational analysis, requiring the association between the initial variable (Behavioral Inhibition × Group) and the outcome (change in infant approach phase avoidance), was already established (see Table 3). For Step 2, a relation needs to be shown between the initial variable and the mediator (maternal encouragement). A further regression analysis was run that confirmed this association, with the interaction between infant behavioral inhibition and group being significantly related to maternal encouragement, β = .27, $p < .05$, once the other study variables had been accounted for. Step 3—which establishes whether the mediator affects the outcome variable when controlling for the initial variable—and Step 4—which establishes the extent of mediation—are estimated in the same equation. Thus, a final regression was run in which maternal encouragement was also included as a predictor of the change in stranger approach avoidance, along with the effects of Behavioral Inhibition × Group. The results are shown in Table 4(a). The overall model was significant, $F(6, 141) = 2.68$, $p < .05$, and explained 10% of the variance, the majority of which was uniquely explained by maternal encouragement.

Table 4(a) shows that maternal encouragement was significantly related to change in stranger approach

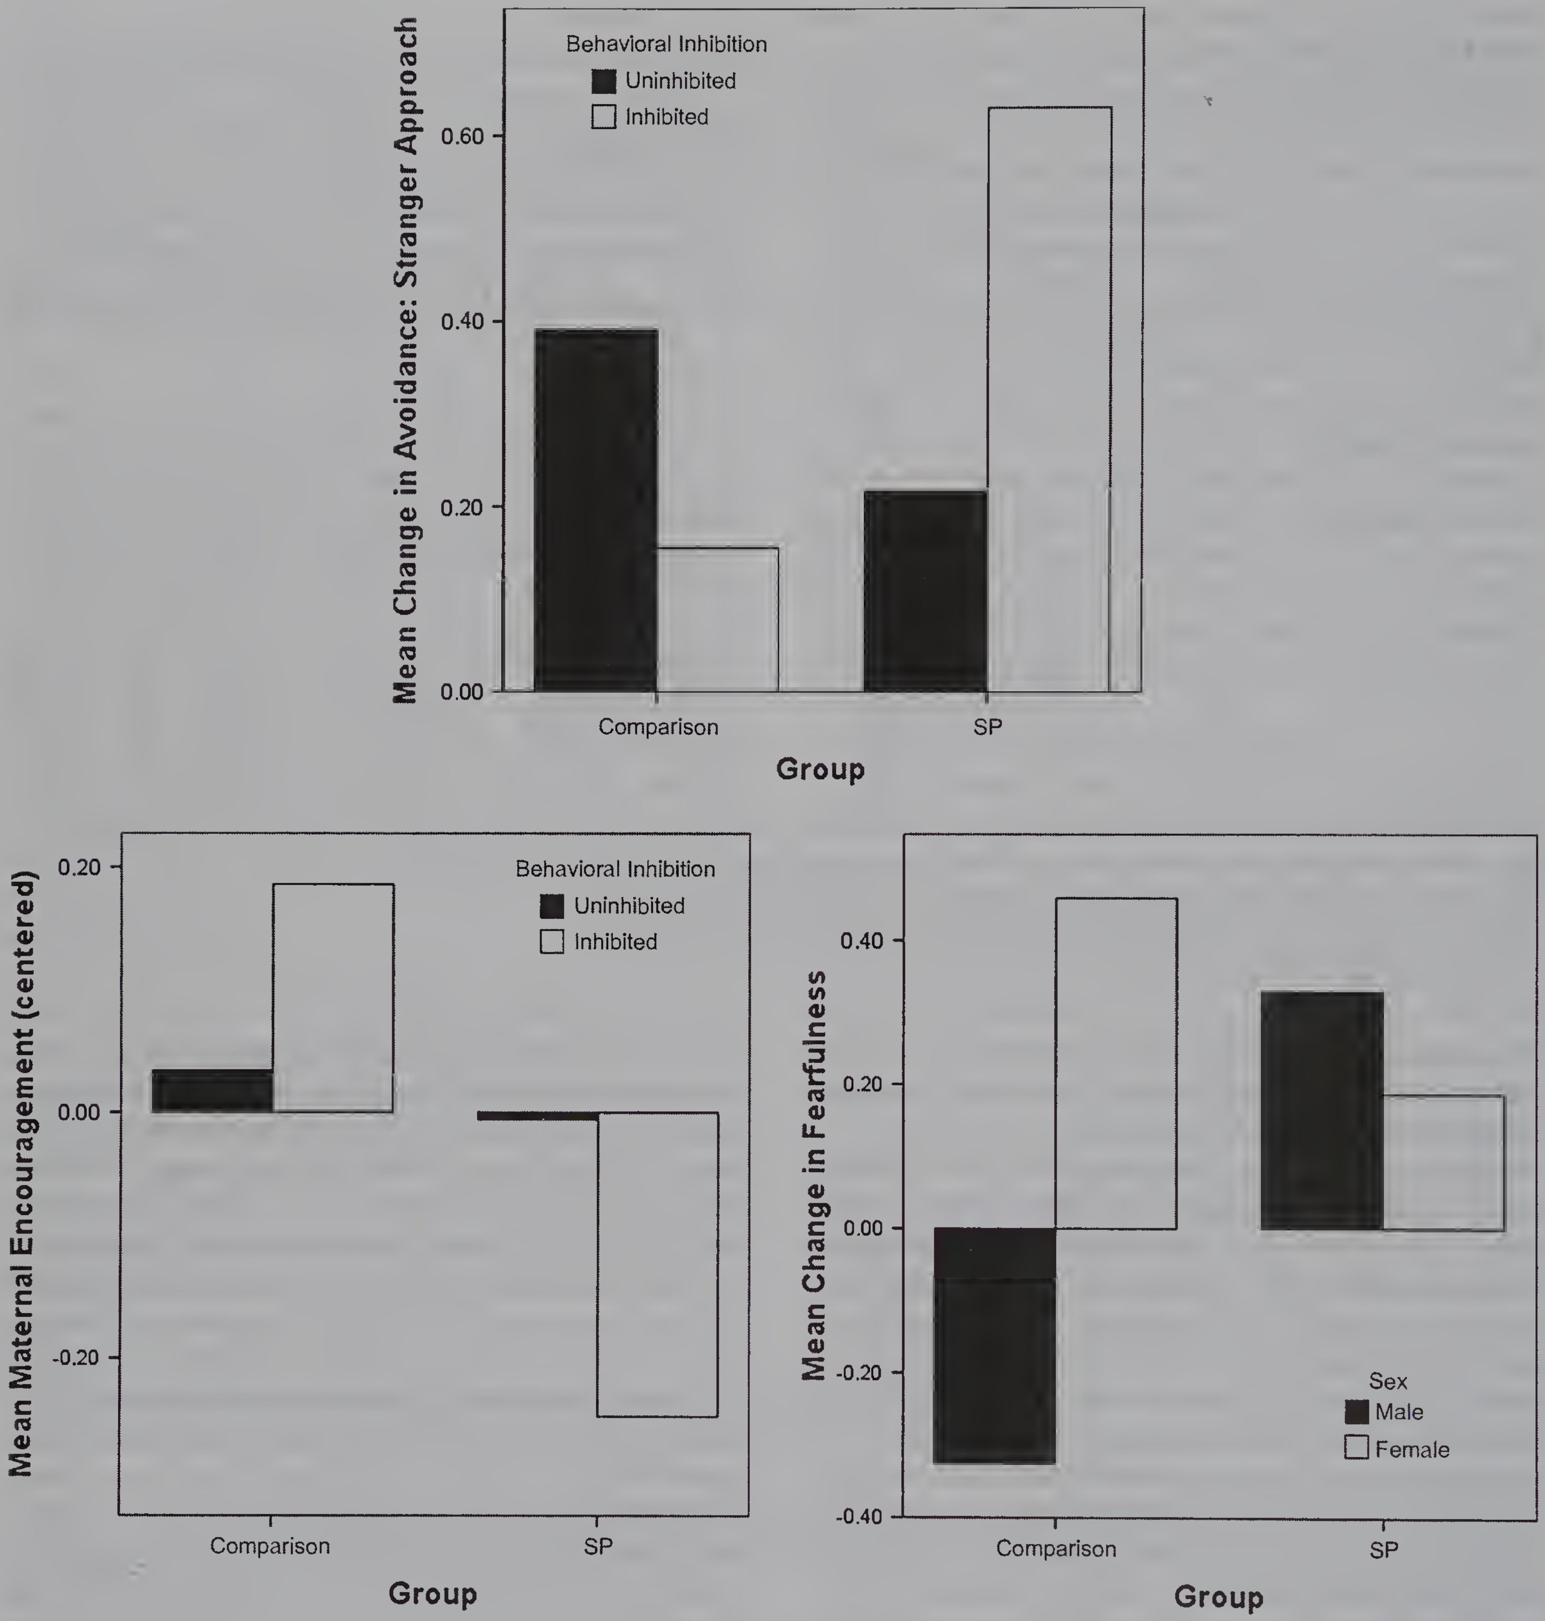

Figure 1. (a) Change in infant avoidance during the stranger approach by maternal group and infant behavioral inhibition. (b) Differences in maternal encouragement by group and infant behavioral inhibition. (c) Change in infant fearfulness by sex and group.

avoidance once the initial variable (Behavioral Inhibition × Group) and the other covariates were accounted for. Table 4(a) also shows that the relationship between Behavioral Inhibition × Group and change in stranger approach avoidance was no longer significant once maternal encouragement was included, indicating a mediating effect of this maternal behavior. To better understand the mediating influence of maternal encouragement, Figure 1b shows how maternal encouragement scores differed by group and behavioral inhibition (maternal encouragement scores were centered to have a mean of zero). It can be seen that index mothers of behaviorally inhibited infants were the *least* encouraging of all groups, and critically, comparison mothers of behaviorally inhibited infants were the *most* encouraging: A post hoc *t* test of the

mean difference (.43) was significant ($p < .05$). Controlling for 14-month maternal encouragement did not alter the overall pattern of these findings.

Infant avoidance of the stranger during the pick-up phase. Neither the principal interaction term of interest (i.e., Behavioral Inhibition × Group) nor other interaction terms (e.g., Sex × Group) significantly influenced change in stranger avoidance during the pick-up phase. Thus, subsequent process analyses were based on the main effects model, which had shown a significant effect of maternal group (see Table 3), whereby infants of mothers with social phobia became more avoidant between 10 and 14 months than infants of comparison mothers.

Exploratory analyses (see Table 2 and the Results section) indicated that maternal expressed anxiety—both during the mother – stranger and infant – stranger interactions—might mediate the relationship between group and change in stranger pick-up avoidance. We provide separate analyses for these two indices of maternal anxiety because they have, arguably, different implications for the mechanisms underpinning the transmission of social anxiety from mother to infant (i.e., indirect and direct transmission, respectively).

The main effects model (Table 3) satisfies Step 1 of the mediation analysis. For Step 2, two regression analyses were conducted—one each for maternal anxiety expressed during the mother – stranger and infant – stranger interactions—that examined the association between maternal anxiety and group. The first analysis, concerning anxiety expressed during the mother – stranger interaction at 10 months, suggested a marginal association with group, $\beta = .16$, $p = .05$, once the other study variables had been accounted for. The second analysis, concerning anxiety expressed during the infant – stranger interaction, suggested that once the other study variables had been accounted for, group was significantly related to maternal anxiety at 10 months, $\beta = .25$, $p < .01$. Because both indices of maternal anxiety satisfied the Step 2 criterion for mediation, two further regression analyses (Steps 3 and 4) were run that included maternal anxiety as a predictor of change in stranger pick-up avoidance as well as group. The results of these models are presented in Table 4(b).

The overall model including maternal anxiety during the mother – stranger interaction was significant, $F(5, 142) = 3.93, p < .01$, and explained 12% of the variance in the change in stranger pick-up avoidance. Maternal anxiety was marginally significant ($p = .05$) and, to some extent, satisfied the criterion for mediation, though it is notable that this mediation was marginal, and group still had a significant impact on change in stranger pick-up avoidance.

The overall model including maternal anxiety during the infant – stranger interaction was significant, $F(5, 142) = 4.23$, $p < .001$, and explained 13% of the variance in change in stranger pick-up avoidance. Maternal anxiety was significant ($p < .05$) and satisfied the criterion for partial mediation; group still had a significant impact on change in stranger pick-up avoidance, although there was a noticeable reduction in the strength of this relationship (see Table 3 for a comparison). Controlling for 14-month maternal anxiety during both the mother – stranger and the stranger – infant interactions did not alter the overall pattern of findings reported in Table 4.

Infant fearfulness of the stranger during the stranger – infant interaction. The first stage of the analyses revealed that neither infant behavioral inhibition nor group (nor their interaction) contributed significantly to change in infant fearfulness (see Table 3). However, the base model indicated that infant sex was significant, with girls becoming more fearful over time. Further investigation, however, showed an interaction between group and sex. Table 5 shows the full model containing initial infant emotional tone, sex, group, and Sex × Group; there were no other significant interactions. The overall model was significant, $F(4, 143) = 4.87, p < .001$, and explained 12% of the variance in change in infant fearfulness. Table 5 shows that all variables made a significant independent contribution. There were main effects for sex and group, which indicated that female infants and infants of index mothers became more fearful between 10 and 14 months. These main effects were qualified, however, by a significant Sex × Group interaction (depicted in Figure 1c): Among comparison mother–infant pairs, male infants became less fearful and female infants became more fearful between 10 and 14 months. Against this backdrop, it is notable that male, as well as female, infants of mothers with social phobia became more fearful from 10 to 14 months. Post hoc t tests confirm that the decrement in fearfulness for male infants of comparison mothers differed significantly from all other groups ($p < .05$) but that there were no other significant differences between the other combinations.

Effects of additional disorders. Finally, we investigated, in exploratory, post hoc analyses, whether the effects of maternal social phobia on infant social responsiveness to the stranger varied according to the presence or absence of other disorders. Thus, the change in infant pick-up avoidance from 10 to 14 months was compared between the group of infants whose mothers had only social phobia and those whose mothers had social phobia plus another diagnosis: No difference was apparent.

Discussion

Offspring of mothers with social phobia are themselves at risk for the disorder (Mancini et al., 1996), but little is known about how early social anxiety develops. Parenting has been considered important, but previous studies of anxious adults and their children have been subject to methodological difficulties. The current study sought to address these problems: using a large, carefully assessed, index sample, all of whom had social phobia, together with a nonanxious comparison sample, we conducted a prospective study in which direct observations of parenting were made under conditions specifically designed to elucidate the core difficulties associated with the maternal disorder and at a time when infants are likely to be particularly susceptible to the impact of these difficulties. We also sought to address the question of whether some infants may be more at risk than others for the development of socially anxious behavior. We therefore took account of infant individual differences in the temperamental constellation of behavioral inhibition, as well as differences in infant exposure to parenting styles associated with the occurrence of child social anxiety.

A central finding of the current study was that infants of mothers with social phobia became progressively more avoidant of social interactions with an unfamiliar adult between 10 and 14 months, particularly during stressful periods of stranger–infant interactions (i.e., during the pick-up phase). Moreover, where infants of mothers with social phobia were behaviorally inhibited, this increase in avoidance extended to the less stressful condition when the stranger made a graded approach. Finally, we found that infant fearful responses to be a function of both maternal social phobia and the infant's sex. Whereas girls in both the study groups showed an increase in their fear of the stranger over time, a pattern consistent with other reports of normal samples (Blackford & Walden, 1998; Gerull & Rapee, 2002), in boys the increase in fearful responses occurred principally in infants of index mothers. The results for infants of mothers with social phobia alone were similar to those of infants whose mothers experienced another disorder in addition to social phobia.

The infant avoidance and fearfulness shown in relation to the stranger's approach and attempts to interact with them in the social referencing paradigm clearly share features in common with the avoidance and anxiety surrounding social contacts of older children and adults with social phobia, and the literature on infant behavioral inhibition suggests that such infant behaviors are predictive of later clinically significant social anxiety (e.g., Stemberger et al., 1995). Nevertheless, it will be important to follow up the current sample to confirm that the

Table 5

infant responses to the stranger we observed do indeed predict subsequent child disorder.

Examination of maternal behavior, both during her own interaction with the stranger and during the stranger's interaction with the infant, helped us clarify some of the processes contributing to the changes in infant social responsiveness. Thus, mothers with social phobia were, as expected, more likely than comparison mothers to show signs of anxiety throughout the experiment. In turn, infants of mothers who expressed such anxiety, particularly as the stranger attempted to interact with them, became more avoidant of the stranger in the pick-up phase over time. We also found that low levels of maternal encouragement to the infant to interact with the stranger at 10 months predicted an increase in infant avoidance during the stranger's approach. These findings demonstrate, therefore, how processes previously shown with normal populations to be important in the transmission of fearful responses from mother to child may also be implicated in the intergenerational transmission of social anxiety in a clinical sample. They also contribute to the corpus of knowledge on the social referencing process by examining effects over time: Thus, although the immediate impact on infant behavior of negative maternal affect in relation to stimuli that may arouse fearfulness is well documented (e.g., Hornik et al., 1987; Moses et al., 2001), in the current study we found an impact of maternal behavior on the infant some months later. Specifically, 10-month maternal behaviors predicted change in infant behavior with the stranger, over and above the effects of any 14-month maternal behavior.

A number of our findings require further comment. The first concerns the role of infant behavioral inhibition. A number of previous studies have reported a link between behavioral inhibition and infant or child social anxiety, but there is a concern that, because of the way in which inhibition is measured (i.e., the inclusion of inhibited responses to *social* stimuli), the two variables may have been confounded. Indeed, a carefully conducted analysis of social and nonsocial inhibition in toddlers by Kochanska (1991) showed the two forms to be largely independent. In view of these concerns, we limited our measure of behavioral inhibition to responses to nonsocial stimuli. In common with the study of mothers with panic disorder by Warren et al. (2003), we did not find an increase in the rate of behavioral inhibition in infants of mothers with social phobia, nor was behavioral inhibition assessed in nonsocial conditions *directly* related to infant social avoidance. Nevertheless, this profile of infant behavior *was* of relevance for the development of infant social responsiveness. Most notable was the fact that mothers with social phobia reacted differently from comparison mothers to this infant behavior. Whereas the comparison group responded by being highly encouraging of their inhibited infants' interaction with the stranger, socially phobic mothers of inhibited infants showed the lowest levels of encouragement. Other studies also suggest that parenting practices that promote child social anxiety are particularly likely to occur in anxious parents in the context of child inhibited, anxious, or negative behavior (Hirshfeld, Biederman, Brody, Faraone, & Rosenbaum, 1997; Manassis & Bradley, 1994; Rubin, Nelson, Hastings, & Asendorpf, 1999; Woodruff-Borden, Morrow, Bourland, & Cambron, 2002). A number of factors are likely to come into play in these associations; thus, anxious parents are prone to overestimate their child's vulnerability, anticipate catastrophic outcomes in potentially threatening situations, and respond by promoting avoidant solutions to challenges (Wood et al., 2003). Translating these findings to the current study, it may have been the case, therefore, that mothers with social phobia underestimated their behaviorally inhibited infants' capacity to cope with the stranger contact, felt that their infants would find it distressing to have to engage with the stranger, and as a consequence, sought to reduce the possibility of contact by not encouraging infant engagement.

It was also notable that the link between infant behavioral inhibition and social avoidance was a function of the mother's response to the infant's inhibition. Thus, behaviorally inhibited infants in the comparison group, whose mothers were highly encouraging, showed the least increase in avoidance of the stranger over time. By contrast, behaviorally inhibited infants of index mothers, faced with the lowest levels of encouragement, showed the greatest increase in avoidance.

Three further aspects of our findings require comment. First, we found that maternal behavior during the stranger's approach and interaction ("direct" phase) with the infant was somewhat more clearly associated with infant responsiveness than maternal behavior that the infant initially observed in the mother–stranger interaction ("indirect" phase). This may have been because the phase of the infant–stranger interaction was more stressful for the mothers (indeed, levels of maternal expressed anxiety were higher at this time). In general, social referencing research has focused on the impact of the earlier phase of the paradigm. The fact that we did not find a strong effect of maternal behavior in this condition may be because, in this phase, the naturally occurring behavior of the mothers with social phobia in our study, while distinguishable from that of comparison mothers, was more subtle than that staged by mothers in experimental studies. Typically, mothers' staged behavior in experimental studies has required careful training, and such behaviors have been found to be considerably clearer and more intense than responses generated under unconstrained conditions (Rosen, Adamson, & Bakeman, 1992). It should be noted, however, that the somewhat greater influence of maternal behavior expressed during the infant's interaction with the stranger in our study is consistent with the results of other studies that have compared the impact of these two phases of the social referencing paradigm (e.g., Feinman & Lewis, 1983; Hornik & Gunnar, 1988).

An increase in infant fearful behavior with the stranger was associated with maternal social phobia only in boys. This may have been because in female infants, the normative increase in fear swamped any effects of maternal mental state. Alternatively, male infants may simply be more vulnerable than females to maternal psychopathology, a phenomenon observed in relation to maternal postnatal depression (e.g., Murray, Kempton, Woolgar, & Hooper, 1993; Weinberg, Olson, Beeghly, & Tronick, 2006). In spite of the association between fearfulness in boys and maternal social phobia, we were unable to establish the mechanisms mediating this link, with none of the maternal behaviors we measured predicting the increase in fear.

Finally, contrary to some suggestions in the literature, we did not find high rates of overcontrolling behavior in mothers with social phobia. However, most studies linking overcontrolling parenting to anxiety in offspring have been based on anxious adults' retrospective reports of the parenting they received or anxious children interacting with their parents. Such studies do not, therefore, directly address the issue of the influence of *parental* anxiety on parenting behavior. In fact, studies of anxious parents and their children, whether involving direct observations (Moore, Whaley, & Sigman, 2004; Turner, Beidel, Robertson-Nay, & Tervo, 2003; Woodruff-Borden et al., 2002), or interview and questionnaire methods (Hirshfeld et al., 1997; Lieb et al., 2000; Rubin et al., 1999), have found little evidence for raised rates of overcontrol; rather, and consistent with our findings, observations show anxious mothers to behave in a withdrawn, disengaged manner.

Our findings have implications for the understanding of the process of intergenerational transmission of anxiety. One mechanism proposed to be important in the clinical literature is the child's modeling of his or her anxious parent's behavior in relation to feared situations (e.g., Gerull & Rapee, 2002; Muris et al., 1996; Rachman, 1977); another is the way in which the parent actively manages the child's behavior, and in particular, the positive benefits of providing support for child autonomy and mastery (Chorpita & Barlow, 1998; Rapee, 1997). Our findings provide support for both processes. Consistent with modeling is the fact that the expression of maternal anxiety was predictive of increasing infant avoidance of the stranger during the stressful pick-up phase. It cannot be determined from the present study whether this increase arose because of a mood contagion effect, whereby the infant becomes generally negative in the face of maternal anxiety and simply generalizes this negativity to whatever is in his or her immediate environment, or whether it is an effect of a social referencing process that is specific to the stranger. Second, our finding that maternal encouragement of the infant's engagement with the stranger showed consistent associations with infant avoidant responses accords with models of intergenerational transmission of anxiety that emphasize parental management.

A number of limitations applied to our study. First, we used a very specific observational frame to assess the transmission of social anxiety. Although this had the advantage that highly relevant processes could be elucidated, more general aspects of parenting were not considered. These include the nature of the mother–child attachment relationship, which previous research has found to mediate continuities between early temperamental characteristics and the development of later behavioral inhibition (Calkins & Fox, 1992; Warren, Huston, Egeland, & Sroufe, 1997). In addition, as the work of Ladd and colleagues has shown (e.g., Ladd & Pettit, 2002), there are important aspects of socialization practices that only indirectly involve the parents, such as whether the child attends day care and is regularly exposed to strangers. Future research should include consideration of these aspects of the child experience. Given the fact that our sample was composed mainly of Caucasian, two-parent, middle-class families, it also needs to be established whether our findings generalize to other populations. A further limitation was the fact that we did not consider the influence of fathers. Research into the effects of maternal depression on child development has shown how the father may act as a buffer against the adverse impact of maternal depression (Conrad & Hammen, 1989), and similar effects may apply in the context of maternal social phobia. Finally, we did not include consideration of genetic mechanisms in the transmission of social anxiety.

Family Resources and Parenting Quality: Links to Children's Cognitive Development Across the First 3 Years

Julieta Lugo-Gil and Catherine S. Tamis-LeMonda
New York University

Reciprocal associations among measures of family resources, parenting quality, and child cognitive performance were investigated in an ethnically diverse, low-income sample of 2,089 children and families. Family resources and parenting quality uniquely contributed to children's cognitive performance at 14, 24, and 36 months, and parenting quality mediated the effects of family resources on children's performance at all ages. Parenting quality continued to relate to children's cognitive performance at 24 and 36 months after controlling for earlier measures of parenting quality, family resources, and child performance. Similarly, children's early cognitive performance related to later parenting quality above other measures in the model. Findings merge economic and developmental theories by highlighting reciprocal influences among children's performance, parenting, and family resources over time.

Economists and developmental psychologists have long been concerned with the factors that promote positive developmental outcomes in children (see Foster, 2002; Haveman & Wolfe, 1995, for reviews). However, the lenses of these disciplines differ in significant ways. Economists investigate the effects of parents' skills and monetary and time resources on their children's educational attainment, health, consumption, and ultimate wealth (Aiyagari, Greenwood, & Seshadri, 1999; Becker, 1964, 1991; Ermisch & Francesconi, 2000). In comparison, developmental psychologists emphasize social capital, especially parenting quality, as a core influence on children's development (Bornstein, 2002; Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Landry, Smith, & Swank, 2006). To date, few studies have integrated economic and developmental perspectives (Guo & Harris, 2000) and few do rarely document

the dynamics of parenting, economic resources, and children's abilities across early developmental periods. The present study addresses these gaps by focusing on reciprocal and unique influences among measures of parental economic resources, parenting behaviors, and children's cognitive performance within and across children's first 3 years.

Integrating Developmental and Economic Perspectives

Building on the traditions of Vygotsky (1978) and Bruner (1983), the developmental literature has long demonstrated the beneficial effects of parenting quality on children's language development, literacy, cognition, and school readiness (Bornstein, 2002; Leseman & de Jong, 1998; Storch & Whitehurst, 2001). Three features of parenting have been acknowledged to promote positive outcomes in young children: sensitivity, cognitive stimulation, and warmth (also termed positive regard or positive affect; Ainsworth, Blehar, Waters, & Wall, 1978; Baumrind, 1973; Bloom, 1993; Bornstein, 2002; Carpenter, Nagell, & Tomasello, 1998; Hart & Risley, 1995; Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 1991; Landry, Smith, Swank, Assel, & Vellet, 2001; Maccoby & Martin, 1983; Matas, Ahrend, & Sroufe, 1978; Nelson, 1973, 1988; Pettit, Bates, & Dodge, 1997; Rohner, 1986; Skinner, 1986; Snow, 1986; Tamis-LeMonda, Bornstein, & Baumwell, 2001; Tamis-LeMonda, Shannon, Cabrera, & Lamb, 2004; Watson, 1985; Woodward & Markman, 1998). *Parenting sensitivity* refers to parents' attunement to their children's cues, emotions, interests, and capabilities in ways that balance children's needs for support with their needs for autonomy. *Cognitive stimulation* refers to parents' didactic efforts to enrich their children's cognitive and language development by engaging children in activities that promote learning and by offering language-rich environments to their children. *Parents' warmth* refers to parents' expressions of affection and respect toward their children and is thought to support skills for learning such as mastery, security, autonomy, and self-efficacy.

In contrast to developmentalists' focus on parenting quality, economists continue to build on the seminal work of Becker (1964) who emphasized the ways in which family resources (e.g., money and time) influence children's learning outcomes (e.g., Blau, 1999; Ermisch & Francesconi, 2000; Haveman & Wolfe, 1995; Hill & O'Neill, 1994; Levy & Duncan, 2000; T. W. Schultz, 1973; T. P. Schultz, 1993). Economists align with developmental psychologists in asserting that parents with fewer resources encounter numerous constraints in meeting their children's needs. However, economists rarely include direct observations of the quality of parent–child interactions in their assessments. Instead, economists conceptualize parenting quality as investments of time and money (Aiyagari et al., 1999; Becker, 1991; Davies & Zhang, 1995; Foster, 2002). Parents who spend more time and monetary resources on children's consumption, education, and care have children who achieve more in terms of cognitive development, educational achievement, and future earnings (e.g., Brown & Flinn, 2006; Hill & O'Neill, 1994; Moore, Evans, Brooks-Gunn, & Roth, 2001).

Although studies by developmentalists and economists have largely been pursued independently, there has been heightened awareness of the need to consider how parenting quality and economic resources *jointly* influence children's developmental outcomes. Studies have revealed that sustained poverty has significant negative effects on children's developmental outcomes and that the quality of parenting plays an important role in mediating these effects particularly at early ages (Bradley et al., 1989; Duncan, Brooks-Gunn, & Klebanov, 1994; Duncan, Yeung, Brooks-Gunn, & Smith, 1998; Garrett, Ng'andu, & Ferron, 1994; Mayer, 1997; National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2005; Yeung, Linver, & Brooks-Gunn, 2002). For instance, Garrett et al. (1994) analyzed the impact of poverty variables and family characteristics on the quality of the home environment (measured by the Home Observation for Measurement of the Environment [HOME]; Caldwell & Bradley, 1984). They found that being born into poverty and the duration and depth of poverty adversely affected the quality of children's home environments. Yeung et al. (2002) considered parental investments, such as the provision of cognitive stimulating materials, and warm and punitive parenting practices, as mediating associations between family income and the developmental outcomes of 3- to 5-year-old children. Although family income was directly associated with children's language and behavioral outcomes, the relationship was mostly mediated by maternal distress and parenting practices. Duncan et al. (1994) found that family income and poverty status predicted cognitive and behavioral outcomes in preschoolers, with effects being largely mediated by the quality of children's home environments.

Remaining gaps. Together, this new wave of studies offers insight into the pathways through which family economic resources and parenting quality jointly influence children's achievement. However, despite recent attempts to document these dual influences, such efforts remain rare and several noteworthy gaps persist.

First, with a few notable exceptions, studies that jointly consider the influences of parenting quality and economic resources on children's outcomes are based on limited measures of one or the other construct. Many studies in the economics literature define parenting in terms of expenditures on children or the amount of time spent with children. Most typically, these indicators of parenting derive from surveys and self-report rather than actual observations of the quality of parent–child interactions (as are more typical in developmental studies). Similarly, studies of family resources and child development often use measures that are not temporally linked to children's age. For example, measures of family income are often based on data from time frames that are either too narrow (e.g., 1 month) or overly broad (e.g., average family income across a span of years). Family income might fluctuate significantly over time due to changes in family structure, the work status of family members, or extraordinary circumstances, such as illness, and therefore should be measured during the specific age at which child development is being assessed. Furthermore, monetary resources are not the only resources that might influence children's cognitive development. Family structure, father residency, and parents' education and language skills have been found to contribute to children's development and academic achievement (Dahl & Lochner, 2005) and should be included in models that examine family resources and child development.

Second, few developmental studies offer a rigorous test of the contribution of parenting to children's outcomes. In particular, issues of selection bias or endogeneity are often not taken into account in analyses. For instance, parents with higher cognitive ability might be able to provide better parenting and also offer more resources to their children (in the form of income, the neighborhood where they choose to live, etc.). However, such characteristics of parents are not usually accounted for in analyses, thus creating selection bias in the estimates of the effects of parenting on children's outcomes. In addition, the associations between parenting practices and children's outcomes are reciprocal. With few exceptions, developmental studies do not regard both children's outcomes and parenting as potential dependent variables. In the absence of rigorous consideration of selection bias and endogeneity, developmental work is at risk of being ignored in the larger social science community (McCartney, Bub, & Burchinal, 2006).

Third, little is known about the contributions of family resources and parenting at *early developmental stages*. Family income has been found to most strongly influence children in the 1st years of life and has led to the recommendation that income-related policies target families with preschoolers (Duncan & Magnuson, 2005). Beyond family income, parent–child interactions shape the long-term trajectories of children already from infancy. For instance, children's literacy experiences influence their language and cognitive development by 14 months of age (Raikes et al., 2006; Rodriguez, Tamis-LeMonda, & Spellmann, 2005), and children's language and cognitive performance are stable from infancy to later ages (Adams, 1990; Campbell & Ramey, 1994; Magnuson, 2005; Mayer, 1997). However, most studies on family resources and parenting are based on families with school-aged children and adolescents. The few studies of "early childhood" include families with children older than 3 years or those with children across a span of ages (e.g., birth to 5 years). Such studies preclude precise statements about the ages at which parenting and family resources affect children in the first years of life.

Fourth, the effects of family resources and parenting on children's development have been typically examined at a single point in time, thereby limiting understanding of the dynamic processes that shape children's abilities across early development. An exception is longitudinal work showing that children who experienced low family income through early childhood showed worse academic achievement outcomes than children who experienced low levels of family income during middle childhood or adolescence (Duncan et al., 1998).

Longitudinal research also sheds light on reciprocal child–environment influences that might feed into children's developing abilities. Forty years ago, Bell (1968) argued against the dominant view in psychology that socialization was a parent-to-child process. He cited convincing research from human and animal studies that indicated the ways in which characteristics of offspring (ranging from physical appearance to skills and behaviors) evoked different responses in parents, which fed back into the development of their offspring. Ideas of reciprocity are further emphasized in current transactional models (e.g., Sameroff & MacKenzie, 2003), which posit that developmental outcomes are the product of continuous, dynamic interactions between children and their environments. In line with a transactional perspective, earlier measures of children's development should affect later measures of parenting just as earlier measures of parenting should affect later measures of children's development.

The limited focus on dynamic family–child influences is particularly evident in studies of low-income families. Studies based on nationally representative data implicitly assume that parenting quality in low-income families influences children's development and mediates the effects of family economic conditions in similar ways as in middle- and upper income families. However, this assumption remains to be tested. In addition, policy concerns around the cognitive and language delays of children in poverty (Brooks-Gunn & Duncan, 1997; Hoff, Laursen, & Tardif, 2002; Votruba-Drzal, 2003) arise soon in development, with disparities already evident by 3 years of age (Ackerman, Brown, & Izard, 2004; Hart & Risley, 1995; Hirsh-Pasek & Golinkoff, 2002; Hoff, 2003; NICHD Early Child Care Research Network, 2001). It is therefore important to take a dynamic approach to examining reciprocal processes in low-income families.

The Current Study

In the current study, we take an integrative approach to understanding the contributions of family income and parenting quality to children's cognitive development in the first 3 years. A main contribution is the rigorous testing of parenting effects on children's development (and vice versa) above the influences of family resources and children's earlier abilities. We consider that family resources affect children's development directly as well as indirectly through the quality of parenting behaviors. We address gaps of previous studies by (a) integrating comprehensive measures of parenting quality and family economic resources that are linked to children's ages in analyses of family influences on children's development, (b) testing for selection bias and considering influences of children's development outcomes on parenting quality, (c) focusing on children's developmental outcomes during the first 3 years, and (d) taking a dynamic, transactional approach to analyses by considering lagged, reciprocal influences between parenting quality and children's development outcomes.

To these ends, we examined a group of low-income families and their children who participated in the Early Head Start (EHS) Research and Evaluation Study. Families were assessed at four specific points in early development (baseline, 14, 24, and 36 months). Our analyses include measures of family economic resources that are developmentally linked to children's age and measures of observed parenting quality. We emphasize processes in low-income families and explore reciprocal effects of family resources, parenting quality, and child development outcomes at adjacent ages.

Method

Participants

Participants were 2,089 mothers and their children drawn from the EHS Research and Evaluation Study.[1] The EHS project was a randomized control experimental evaluation conducted in 17 sites across the United States. Study participants were low-income families who had sought assistance from local EHS community agencies between 1996 and 1999. Data on family characteristics and functioning, parenting and children's health, and cognitive outcomes were obtained when mothers applied to EHS (i.e., baseline), as well as from interviews, observations, and direct child assessments when children were 14, 24, 36 months. These interviews were augmented with telephone interviews at 6, 15, and 26 months after the baseline interview.

The EHS Research and Evaluation Study originally recruited 3,001 mothers and their children. However, 355 of the initially recruited participants dropped out of the study soon after being selected and therefore had virtually no data. Of the remaining 2,646 families for whom some data existed, we included 2,089 families who had data on children's outcomes, parenting quality, and family income from *at least one of the three assessments*. This sample did not differ from the sample of families who did not have at least one measure of parenting, one child outcome, and one measure of family income (N = 557), with the exception that the participants without any data on these measures were more likely to be Black.[2]

Table 1 presents demographic characteristic of the sample of 2,089 low-income children and their families. Almost 71% of the families in the sample had annual income below the poverty line at the time of recruitment, and the average annual family income reported was $11,532.4 (in 2003 dollars). About one fifth of the mothers were adolescents when their children were born and all mothers averaged 22.4 years. At baseline, about a quarter of the mothers were married and living with their husbands. Slightly more than half of the children were male and more than 60% were firstborns. The mothers in the sample were from White, African American, and Hispanic backgrounds. About half of the mothers had at least a General Educational Development Test (GED) or high school degree at baseline and subsequent assessments. Most of the mothers reported that English was their first language.

Procedures

Home visits at 14, 24, and 36 months consisted of a 45-min parent interview, direct assessments of

Note. EHS = Early Head Start.

children's cognitive abilities, a 10-min videotaped session of semistructured mother–child free play, and a videotaped dyadic challenge session (highchair task at 14 months, teaching tasks at 24 and 36 months). Interviewers also completed a checklist on their observations of the home environment at the end of each visit. At the 24-month assessment, mothers' cognitive and language skills were assessed using the Woodcock–Johnson (WJ) Picture Vocabulary Test (WJ–III Tests of Achievement [Standard Battery]; Woodcock & Johnson, 1989).

For the *free play sessions*, mothers were presented with three bags containing a book and a standard set of age-appropriate toys. At the 14- and 24-month assessments, the bags contained a book (*Good Dog Carl* and *The Very Hungry Caterpillar*, respectively), a cooking set, and a Noah's Ark set with animals. At the 36-month assessment, the bags contained a book (*The Very Hungry Caterpillar*), a cash register and grocery items, and a container of interlocking blocks. Mothers were instructed to begin with Bag 1 and to finish with Bag 3 and were encouraged to play with their children as they ordinarily would and to face the camera.

The challenge task at 14 months consisted of mother placing her infant in a booster chair, with the infant's back toward the mother. Mothers sat behind the infant and were asked to draw a picture of the family while the infant remained in the chair without any objects for a period of 4 min. Mothers were told "I'd like you to put [Child's Name] in this chair and strap him/her in. You will then sit in this chair behind your baby. We'd like your child to remain in the chair for 4 minutes while you draw a picture of your family. Feel free to take care of your child as you normally would, but we ask that you not provide him/her with any objects and that you not remove him/her from the chair." The challenge task at 24 months consisted of mothers teaching their toddlers how to sort blocks according to color or learn words for articles of clothing shown in a book. Mothers selected the task that they felt their child did not know. Once they selected the task, they were asked to sit on a mat and to let the experimenter know when they had finished teaching the child. The challenge task at 36 months consisted of the child being presented with three puzzles of increasing difficulty one at a time. Mothers were told that the puzzles were challenging for 3-year-olds. They were instructed to first let the child work on each puzzle alone, and then, they could give the child the help they felt the child needed. All mother and child interactions were videotaped and subsequently coded by staff at the Center for Children and Families, Columbia University, Teachers College.

Measures

All measures in this study, except family income, were based on data obtained during home visits. Family income was measured at baseline and at the telephone interviews conducted at 6, 15, and 26 months after the baseline interview. These income data were reconstructed to create an income timeline that enabled us to estimate household annual income for the periods leading up to each of the three child ages (14, 24, and 36 months).

Child cognitive outcomes. At the 14-, 24-, and 36-month assessments, cognitive development was assessed with the Mental Development Index (MDI) of the Bayley Scale for Infant Development, Second Edition (BSID – II; Bayley, 1993). The MDI assesses vocalizations, language skills, memory, problem solving, early number concepts, classification abilities, generalization, and social skills. This indexed scale has a mean of 100 and a standard deviation of 15. The MDI has shown adequate internal consistency and interrater reliability.[3] A score of 85 – 100 in this scale is within normal limits.

Background factors. Several background factors were included as controls for initial conditions of mother and child. These were conceptualized as characteristics of mothers and children that do not change over time and are likely to influence parenting quality and children's outcomes. Background factors were children's gender, birth weight, mother's age at childbirth, ethnicity, primary language, and mothers' cognitive skills as indexed by the WJ.

Children's characteristics such as gender and birth weight might play an important role in determining parenting quality and children's developmental outcomes. For example, it has been found that girls present a slight advantage over boys during early stages of cognitive and language development (Bornstein, 2002; Fenson et al., 1994). In addition, it has been found that birth weight significantly predicts later development (Bradley, Whiteside, Mundfrom, & Blevins-Knabe, 1995; Landry et al., 2006; Shenkin, Starr, & Deary, 2004).

Maternal characteristics and skills influence the quality of parenting styles and child development outcomes (Bornstein, 2002). For instance, teenage mothers tend to be less mature and lack a well-established maternal self-definition (Brooks-Gunn & Chase-Lansdale, 2002) and their children perform less well than those of older mothers on measures of cognitive and language development (Keown, Woodward, & Field, 2001; Rodriguez et al., 2005). Mothers' ethnicity and/or primary language relates to how responsive or intrusive mothers are in their interactions with the children (Ispa et al., 2004) and to maternal teaching styles and shared narratives in the preschool years (Melzi, Paratore, & Krol-Sinclair, 2000; Paratore, Melzi, & Krol-Sinclair, 2003). Finally, measures of mothers' cognitive abilities, as assessed through standardized instruments, relate to parenting and children's cognitive outcomes (e.g., Yeung et al., 2002).

Here, dichotomous indicators were used for child gender, birth weight (< 2,500 g vs. other), mothers' age (< 18 years old at child's birth vs. other), ethnicity (contrasts for African American vs. other and for Hispanic vs. other), and mothers' primary language (1 indicating English).

Family resources. We considered four measures of family resources: mother's own reading frequency, mother's educational achievement, parental living arrangements, and income per capita in the family. Summary statistics of these measures are presented in Table 3. Although these four measures do not fully capture a family's human capital (conceptualized as all resources that enable individuals to achieve well-being), they each contribute in significant ways to children's and family's well-being. For instance, mother's own reading frequency and educational achievement indicate maternal ability to teach and stimulate learning. Father's residency reflects the availability of additional financial and parenting resources.

Income per capita in the family relates to wealth and consumption resources allocated to children.

Mothers' educational achievement was represented by mothers' years of education at the time of the assessment. Mother's own reading frequency was assessed with a single item coded on a 5-point Likert scale (5 = *daily reading*, 1 = *reading a few times per year*, 0 = *never reads*). Father residency was coded dichotomously at each assessment, representing whether the biological father lived with the mother and child at the 14-, 24-, and 36-month assessments.

Family income was measured at baseline or recruitment and at the assessments that took place at 6, 15, and 26 months after the baseline interview. Given the goal of including repeated measures of annual monetary resources that temporally aligned with the child assessments, we computed the amount of money received by all family members (including the mother) for the periods in which each child in the sample was 0 – 14 months, 14 – 24 months old, and 24 – 36 months. Therefore, family income represented the total amount of money received by the mother and the members of the family, as reported by the mother. It included public assistance and other transfers (e.g., food stamps) because the question was not limited to the amount of money *earned* by family members but excluded taxes and deductions. From these multiple assessments, monthly family income was calculated for each of the 36 months from the child's birth date through the child's third birthday. These month-by-month calculations were summed to create totals for 0 – 14 months, 14 – 24 months, and 24 – 36 months income figures. Whenever data were not available for a portion of a development period, the available monthly income data were prorated so as to span the relevant developmental periods. To provide a more accurate portrayal of the amount of monetary resources available to children at each age, income per capita was used in analyses.

Parenting quality. Parenting quality was based on a composite score of several dimensions of parenting that were assessed from three protocols at each age: videotaped mother – child play (three-bag task), videotaped challenge tasks (high chair and teaching), and the HOME scale. First, maternal supportiveness was assessed from free play at 14, 24, and 36 months. Supportiveness was the average of mothers' ratings on three Likert-scaled items: maternal sensitivity, positive regard, and cognitive stimulation (1 = *very low* to 7 = *very high* on each dimension), following the established precedent of the EHS Consortium studies (e.g., Berlin, Brady-Smith, & Brooks-Gunn, 2002; Love et al., 2005; Shears & Robinson, 2005; Tamis-LeMonda et al., 2004). Sensitivity reflected the extent to which the mother was responsive to her child's distress and nondistress cues; positive regard reflected mothers' demonstration of love, respect, and admiration toward her child; and cognitive stimulation reflected mothers' attempts to teach her child so as to enhance perceptual, cognitive, and linguistic development. These items covaried strongly at all ages (r ranges from .60 to .62, .53 to .68, and .50 to .71 at 14, 24, and 36 months, respectively. All were significant at the .01 level). The supportiveness composite also showed adequate internal consistency at each age (Cronbach's αs = .82, .83, and .82 at 14, 24, and 36 months, respectively).

Second, interviewers completed the HOME scale (Caldwell & Bradley, 1984), and total HOME scores were used. This scale rates the quality of the home environment including provision of learning materials, activities (e.g., reading), and observations of mother and child verbal interactions during the full duration of the home visit.

Finally, mother – child interactions were coded from the videotaped challenge task at each age (high-chair task at 14 months, teaching task at 24 months, and puzzle task at 36 months). At 14 months, maternal sensitivity and positive regard were coded on 7-point Likert scales and summed to create a composite supportiveness score. At 24 months, mothers' teaching was coded using the teaching scale of the Nursing Child Assessment Satellite Training (NCAST; Barnard, 1976). This scale coded a total of 50 binary items reflecting mother's sensitivity, responsiveness to child distress cues, cognitive growth fostering, and social-emotional growth fostering. These items were assessed as present or absent and summed to a total score (Barnard, 1976). At 36 months, scores on mothers' supportive presence and quality of maternal assistance were rated during the teaching and puzzle tasks (1 = *very low* to 7 = *very high*). Supportive presence measured the mother's emotional availability and physical and affective presence during the task and quality of assistance focuses on the instrumental support and assistance provided by the mother during the task.

Because the coding of the three parenting protocols yielded scores on different metrics, scores were z transformed and then summed into a total parenting quality score at each age. Bivariate correlations between the three parenting quality scores were significant at the $p < .01$ level at all ages (r ranges from .31 to .45, .30 to .42, and .41 to .51 at 14, 24, and 36 months, respectively). Confirmatory factor analysis was then run to verify that the three measures of parenting loaded onto a single factor at each of the three ages. Table 2 presents the results from this analysis. The strongest loadings were obtained for

Table 2
Factor Loadings of Confirmatory Factor Analysis of Parenting Quality Aspects

Measure and variable	Unstandardized factor loading	Standardized factor loading	R^2
14-month parenting quality			
14-month Maternal Supportiveness score	1.00[a]	0.70	.49
14-month HOME score	3.03*	0.63	.40
14-month High Chair Task score	0.99*	0.48	.23
24-month parenting quality			
24-month Maternal Supportiveness score	1.00[a]	0.69	.48
24-month HOME score	2.94*	0.62	.37
24-month Teaching Task score	2.82*	0.50	.25
36-month parenting quality			
36-month Maternal Supportiveness score	1.00[a]	0.71	.50
36-month HOME score	4.19*	0.58	.34
36-month Puzzle (Teaching) Task score	1.21*	0.72	.52

[a]Not tested.
$^*p \leq .05$.

the HOME score at all ages. However, as indicated by the standardized estimates, the largest correlations with the parenting factor were seen for maternal supportiveness during free play at 14 and 24 months and by supportiveness in the teaching task at 36 months. All the unstandardized estimates that were not normalized to be 1 were significant at a level of $p <$ .05. As indicated by the R^2 of each indicator, parenting quality explained between 23.4% and 51.7% of the variances of the indicators. Because all factor loadings were significant, the creation of composite constructs of parenting at each age was deemed to be appropriate. The parenting quality composite at each age showed sufficient internal consistency (Cronbach's αs = .63, .62, and .70 at 14, 24, and 36 months, respectively).

Results

We first present descriptive statistics of background measures, parenting quality, family resources, and child cognitive performance, followed by bivariate associations among these measures. Next, structural equation modeling (SEM) tests associations among measures across the three ages. The conceptual model that guided the structural equation analyses is presented in Figure 1. At each age (14, 24, and 36 months), we assumed that family resources (family income, father's residency, etc.) influence child outcomes both directly and indirectly (through parenting quality). Parenting quality was assumed to directly affect children's outcomes at each age. We controlled for earlier experiences by linking parenting quality at 24 and 36 months to previous parenting quality and by linking child cognitive performance at 24 and 36 months to previous child performance. We hypothesized reciprocal effects between children and parents. Thus, the model includes lagged effects from children's performance at each age to parenting quality at the adjacent age and vice versa (diagonal paths). Family background factors (e.g., mothers' and children's demographic characteristics) served as controls.[4]

Descriptive Statistics

Descriptive statistics for all measures and constructs appear in Tables 3 and 4. As indicated in Table 3, mothers averaged 89 on the WJ Test of Achievement, which is approximately 0.75 *SD* below the population norm. Children's Bayley MDI scores were within the normal limits but below population norms at all ages. Bayley scores declined significantly from 14 to 24 and 36 months, as indicated in a repeated measures analysis of variance. This drop may reflect changes to the skills being tapped by the Bayley MDI at earlier versus later ages. That is, the Bayley MDI at 14 months in part measures motor skills, whereas at 24 and 36 months, Bayley items increasingly tap language development.

Table 4 presents summary statistics of mothers' own reading frequency, family income, and parenting quality. On average, mothers were reading on their own between a few times a month and once a week. Sample averages of total family income and income per capita (all in 2003 dollars) for the considered developmental periods were stable over time. The averages at 24 months shown in Table 4 appear to be lower than at other ages because family income amounts at 24 months represented economic resources for the period between 14 and 24 months, which is only a 10-month period. The average income per capita ranges from about $4,600 during the 0- to 14-month period to about $5,100 in the 24- to 36-month period, with average family size between four and five family members. Although summary statistics are presented for both total and per capita income, analyses were based on income per capita.

Bivariate Associations

Table 5 presents bivariate correlations between the background factors and the parenting quality score at each age. The strongest associations are between mothers' scores on the WJ Test of Achievement and parenting quality at each age. The maternal primary language indicator (=1 if the primary language is English) also relates to parenting quality, but associations decrease over time (*r*s = .20, .13, and .11, at 14, 24, and 36 months, respectively, all with $p \leq .01$). The indicators for being a teenager, African American, and Hispanic are all negatively and significantly associated with the quality of parenting score but again decrease over time. Neither child gender nor low birth weight related to parenting quality.

We calculated bivariate correlations between income per capita in the family, mother's years of education, mother's own reading frequency, father residency, and parenting quality at each age. Income per capita was positively associated with all variables at each age. Mothers' own reading frequency was very modestly associated with income per capita in the family at each age ($r = .06$, $p \leq .05$ at 14 months; $r = .11$, $p \leq .01$ at 24 months; $r = .07$, $p \leq .01$ at 36 months). Income per capita related most strongly to parenting quality (*r*s = .26, .25, and .28, at 14, 24, and 36 months, respectively, all with $p \leq .01$). The parenting quality score was also associated with all other variables at each age, with associations being strongest to mothers' years of education (*r*s = .45, .37, and .38, at 14, 24, and 36 months, respectively, all with $p \leq .01$).

Table 6 presents the associations between background factors, family resources, and parenting quality scores and children's Bayley MDI scores at each age. Both family resources and parenting scores correlated with children's Bayley scores at all ages. The weakest associations were between mothers' background factors at 14 months and children's Bayley scores at 14 months and between children's

Bayley scores at 14 months and later family resources at 24 and 36 months.

Finally, income per capita, parenting quality, and children's cognitive development outcomes were stable across the three assessments, as suggested by bivariate correlations of each variable at a given time with itself at the subsequent assessment. In particular, parenting quality was strongly stable and stability

Table 5
Bivariate Correlations of Background Variables to Parenting Quality

coefficients increase over time ($rs = .62, .63$, and .65, for comparisons of 14–24, 14–36, and 24–36 months, respectively, all with $p \leq .01$).

Together, these findings indicate that background factors and family resources are associated with parenting quality at each age and that background factors, family resources, and parenting quality consistently predict children's Bayley scores. Thus, testing a model that includes repeated assessments of these sets of measures is justified. Moreover, in light of the high stability in child cognitive performance and parenting quality across 14-, 24-, and 36-month assessments, the inclusion of earlier measures of child performance and parenting quality produces a very conservative estimate of the effects of parenting and income on children's performance at later ages.

Estimation Strategy

SEM was used to test paths between background factors, family resources, parenting quality, and child outcomes across the three assessments. This estimation approach simultaneously tests associations between all measures in the proposed model (Schumacker & Lomax, 1996; Yeung et al., 2002). In addition, SEM estimates direct and indirect effects of predictors in a longitudinal design. We used the Mplus (Muthén & Muthén, 2004) program to estimate our model. Mplus uses maximum likelihood and permits estimation of structural equation models for which some or all variables have missing data. In this estimation procedure, the likelihood function is conditioned to the missing data in the model, and the nonmissing data are used to find the parameters that maximize the conditioned likelihood function. Thus, this estimation method uses all the information that is available from the data. This technique has been shown to yield better estimates than estimation methods that rely on case deletion or single imputation (McCartney et al., 2006; Schafer & Graham, 2002).

Model Fit

We present several statistical evaluations of the model in Table 7. Specification 1 reports results of a model in which direct paths from the family resources variables (i.e., family income per capita, mother's years of education, father's residency, and

$^*p \leq .05$. $^{**}p \leq .01$.

mothers' reading frequency) to the children's outcomes at each age are *excluded*. Specification 2 reports the same results for a specification in which all paths from the model presented in Figure 1 are included. Disturbance terms and unanalyzed associations in background factors and resources variables are not depicted but were included in all estimations.

Because Specifications 1 and 2 represent nested models, we performed a likelihood ratio test to assess which model provided a better fit. The test statistic shown in Table 7 (a χ^2 value with 12 *df*) indicates that at a .05 significance level, it is not possible to reject the null hypothesis that the paths of the family resources variables to the child cognitive outcomes are statistically equal to zero (based on a critical χ^2 value of 21.03). This result suggests that the effects of family resources on child outcomes are completely mediated by parenting quality at each age.

We also tested Specification 1 against a model that excluded the paths between past child outcomes and current parenting and between past parenting quality and current child outcomes (Specification 3). Similarly to Specification 1, Specification 3 excludes direct paths from family resources variables to child outcomes. Again, a likelihood ratio allowed us to assess whether the reciprocal paths between child outcomes and parenting quality significantly contribute to a better model fit. The test statistic (a χ^2 value with 4 *df*) indicates that at a .05 significance level, we can reject the null hypothesis that the paths of past child outcomes to current parenting quality and paths from past parenting to present child outcomes are statistically equal to zero (based on a critical χ^2 value of 9.49). This result suggests that reciprocal effects between children and parents exist.

Given the results of these tests, we next adopted the more parsimonious specification of the model that excludes direct paths from the family resources variables to the child outcomes at each age but considers reciprocal paths between child outcomes and parenting quality (Specification 1).

Overall, the fit indices indicate that Specification 1 provides a better fit than Specifications 2 and 3. The standardized root mean square residual and the root mean square error of approximation for Specification 1 are below .05, which can be considered a good fit. The Tucker–Lewis index (TLI) and the comparative fit index are above .90 for Specification 1, which in general is considered a good fit. The TLI for Specifications 2 and 3 are slightly below .90. The chi-square values of model fit were also computed for the three specifications. However, because this statistic is sensitive to the sample size (N = 2,089 in the present study), its value for all specifications was significant. Given that all other fit indices reported in the present study take into account the value of the chi-square and the degrees of freedom in our model, we considered that the values obtained from these indices provide enough evidence that the model we propose fits the data well.

Finally, the proportion of explained variance (R^2) for each of the dependent variables in the model also provides a measure of model fit. The proportion of explained variance of the Bayley MDI at 14 months is close to 10% and it increases to 32% and 40% at 24 and 36 months, respectively. The model also explains a significant proportion of the variance of parenting quality at each age. In all specifications, the proportion of explained variance across parenting quality scores ranges from 38% at 14 months to almost 50% at 36 months. Increasing proportions of explained variance across time suggest cumulative

Table 7
Model Fit

Specification	SRMR	RMSEA	TLI	CFI	Log likelihood	Chi-square value of log-likelihood difference
1. Direct paths from family resources to child outcomes are excluded	.02	.04	.90	.93	−57,303.43	
2. Direct paths from family resources to child outcomes are included	.02	.04	.89	.93	−57,296.49	
Difference between Specifications 2 and 1					6.94	13.89
3. Reciprocal paths from child outcomes to parenting and vice versa are excluded	.03	.04	.89	.91	−57,335.26	
Difference between Specifications 3 and 1					31.83	63.64

Note. The differences in log likelihoods are absolute values. SRMR = standardized root mean square residual; RMSEA = root mean square error of approximation; TLI = Tucker–Lewis index; CFI = comparative fit index.

influences in children's cognitive development and parenting quality.

Parameter Estimates

Figure 2 presents standardized (in bold font) and unstandardized estimates of the paths of the model in which the effects of family resources variables on child outcomes are mediated by the quality of parenting (Specification 1).[5]

At all ages, the largest effect on parenting quality from a family resource variable was obtained for mothers' years of education, with higher maternal education being associated with higher parenting quality. Fathers' residency and mothers' reading frequency were positively associated with parenting quality at 24 and 36 months (net of other measures in the model), although effect sizes were small. Higher income per capita in the family is also related to higher parenting quality, although the associations were small relative to others in the model. The effects of the family resources variables on parenting quality were small at all ages. However, these effects remained significant at 24 and 36 months even after controlling for past parenting quality. The strongest effects in the model were the associations between current and past parenting quality, revealing high levels of stability being already established at these early child ages. The standardized estimate of the path from parenting quality at 14 months to parenting quality at 24 months was .52, and the estimate of the path from 24 months to 36 months parenting quality was .53. Parenting quality at each age had a positive direct effect on child cognitive outcomes. The effects of parenting quality on child outcomes were moderate, but these effects were still significant even when the strongest effects on child cognitive outcomes were included—namely, prior child outcomes. Finally, lagged parenting quality was positively associated with child outcomes at 24 and 36 months, and lagged child outcomes had positive effects on parenting quality at 24 and 36 months. Although these estimates were small, they suggest the presence of reciprocal effects between children's abilities and subsequent parenting behaviors under extremely conservative tests.

Male child indicator	−2.10*	−.97*	−.49*
Low birth weight indicator	−6.63*	−3.08*	−1.54*
Teen mother indicator	−.28*	−.57*	−.40*
African American indicator	−.16*	−2.32*	−1.66*
Hispanic indicator	−.35	−.71	−.50
Mother's primary language is English indicator	−.18	−.36	−.26
Mother's score on WJ Test	.07*	.14*	.10*

Note. Statistical significance of indirect effects is based on bootstrap standard errors. MDI = Mental Development Index; WJ = Woodcock–Johnson.
$^*p \leq .05$.

Table 8 presents estimates of the indirect effects of family resources variables on children's outcomes and of the total effects (i.e., direct and indirect [through parenting] effects) of background factors on children's outcomes. We report unstandardized estimates for interpretation purposes.[6] These unstandardized coefficients represent the effect of a unit increase in family resources variables and background factors on the child's Bayley MDI score. The estimates reported in Table 8 show small effects of a unit increase in family resources variables on child outcomes. For instance, an increase of 1 year in maternal education at 14 months produces an increase in the score on the Bayley MDI of less than one fourth of a point. Likewise, increases of 1 year in maternal education at 24 and 36 months create increases in the Bayley MDI score of about one ninth of a point. Similar effects on child outcomes were found in the case of mother's own reading habits and father's residency. The effect of income per capita on child cognitive outcomes was small and weakly increasing over time. According to the estimates presented in Table 8, an increase of $10,000 in the income per capita for the period between birth and 14 months of age would increase the score on the Bayley MDI by almost half a point. For the period between 14 and 24 months, a similar increase in income per capita would increase the score on the Bayley MDI at 24 months by close to a point. Finally, an increase of $10,000 in the income per capita for the period between 24 and 36 months of age would increase the score on the Bayley MDI at 36 months by about half of a point. Although each of these influences is small by itself, they are significant, and the total accumulation of these predictors on children's Bayley scores is meaningful.

We consider important to compare the effects of the family resources variables on child outcomes to the effects of the background factors. According to the results reported in Table 8, being a male child decreases the score on the Bayley MDI at 14 months by 2.1 points. At 24 and 36 months, the negative effects of child gender on child outcomes were smaller but still significant. Low birth weight had significant negative effects on cognitive outcomes at all ages. At 14 months, having low birth weight decreases the score on the Bayley MDI by 6.6 points. Although this negative effect declines over time, it was still significant at 36 months. Being a teen mother at the birth of the child and being African American had negative effects on the Bayley MDI scores at all ages. Being Hispanic and the mothers' primary language did not have significant effects on the child outcomes. Finally, mothers' language and cognitive skills, measured by their score on the WJ Picture Vocabulary Test, had small effects on the child cognitive outcomes at all ages. For example, at 14 months, an increase of 10 points in the mothers' WJ Test would increase the score on the Bayley MDI by close to a point. At 24 and 36 months, a similar increase in the mothers' WJ would create an increase in the Bayley MDI scores of 0.14 and 0.10, respectively. Regarding the effect of background variables on parenting quality, mothers with higher language and cognitive skills provided higher parenting quality. However, this effect was close to zero. Teenage and African American mothers tended to provide lower parenting quality.

Selection Bias

We were concerned about potential selection bias (from included and excluded variables) in our estimates. Economic or social resources might appear to affect child development outcomes but do so via their association to other measures not included in the model as well as unobserved characteristics and abilities of parents and children. Dahl and Lochner (2005) addressed this issue by using an estimation strategy that accounts for measurement error and omitted variable bias when analyzing the effects of income on children's math and reading outcomes. However, the authors did not consider the role of parenting quality and family resources other than income on determining child cognitive outcomes. NICHD Early Child Care Research Network and Duncan (2003) examined the effects of child care quality on children's cognitive development at preschool entry. As one way to assess whether selection bias might account for the identified associations between child care and child outcomes (e.g., characteristics in parents and children might underlie both child care choices and child measures), the authors ran a set of regression equations in which they progressively added controls to their models and compared estimates across models for their key associations. This analytic approach is based on earlier versions of the work of Altonji, Elder, and Taber (2005), which rests on the assumption that control variables included in nested models represent a subset of all possible controls. If the magnitude of the change in the coefficients of interest (e.g., child care to child outcome effects) is large, then selection bias is likely. If changes to coefficients are small or negligible, it suggests little additional bias from unobservable variables (Altonji et al., 2005).

Adopting this approach, we estimated changes to model coefficients for parenting effects in models that included the background variables in Figure 1 against models that included a larger set of controls. The additional controls were time invariant based on measures of parent and child characteristics gathered at the baseline assessment for the EHS Research and Evaluation Project as well as maternal depression measured by the Center for Epidemiological Studies Depression Scale (Radloff, 1977). These added controls included childbirth order, number of moves in the past year, family income as percentage of the poverty line, urban versus rural indicator, maternal employment status, maternal marital status, welfare receipt, and maternal education at baseline. The magnitude of the change of the effects of parenting quality on child outcomes in the contrasting models was negligible, even when measured in terms of standard deviations. (Maternal depression related inversely to child outcomes and the urban indicator related positively to child outcomes.) Parenting at all three assessments retained its significance in the fuller model. This suggests that there was little additional bias from unobserved variables.

Discussion

Despite widespread consensus that both parenting and economic resources matter for children's development, few studies have investigated the joint and unique influences of economic resources and parenting quality to children's development. This gap is particularly notable for infants and toddlers from low-income families. Furthermore, the dynamic nature of parenting behaviors and other family resources (e.g., mothers' education, father residency) is rarely examined. Thus, little is known about the effects of earlier experiences on current and later child outcomes and how child cognitive development reciprocally affects parenting behaviors over time.

In this study, we investigated the effects of parenting quality and family economic resources on the cognitive development of 0- to 3-year-old children from low-income families who participated in the EHS Research and Evaluation Study. The measure of parenting quality was based on direct observations of mother–child interactions and the home environment. With respect to family economic resources, we considered income per capita in the family during three developmental periods in the first 3 years, thereby matching family income to the time frame of child testing. In addition, models included other measures of families' resources such as maternal education, maternal reading habits, and fathers' residency. Finally, we analyzed mutual and dynamic influences of parenting quality and child cognitive outcomes across adjacent ages.

We found that the effects of family economic resources on children's outcomes at 14, 24, and 36 months were completely mediated by parenting quality at each age. Income per capita in the family and the other family resources variables had statistically significant indirect effects on child outcomes at every age. Although the effects of family income and other family resources on parenting quality were small, they remained unique predictors even after controlling for prior parenting quality. In this investigation of early development, economic resources influenced children primarily through parents' behaviors, which accords with the finding that socioeconomic status indirectly affects children's performance on language outcomes and academic achievement through its influence on parents' beliefs and behaviors (Davis-Kean, 2005; Raviv, Kessenich, & Morrison, 2004). It is likely that economic resources also influence children's development through other paths, including child-care settings, schools, peers, and neighbors, as children age.

Parenting quality also had unique effects on current child cognitive outcomes even after considering child outcomes at prior ages. Moreover, the effects of current parenting quality on current child cognitive outcomes were significant even after controlling for parenting quality at previous ages. Therefore, we present an extremely conservative approach to modeling economic resources and parenting influences on child development.

We found that the effects of lagged parenting quality on current child outcomes, net of the effects of lagged child outcomes, were significant. Our results also showed that past child cognitive outcomes significantly influenced current parenting quality. Furthermore, a model with reciprocal effects from children to parents and vice versa provided a better fit to the data than a model that did not include those paths. The presence of significant reciprocal effects, even after considering prior parenting experiences, suggests that although parenting is stable over time, parents continue to modify their behaviors in response to children's developmental achievements. Beyond cognitive development, other characteristics in children, such as temperament and even physical attributes, have been shown to affect parenting over time; thus, children are active participants in the construction of their own experiences.

Finally, these findings support a cumulative model of developmental influence. The estimated model resulted in increasing explained variance of the Bayley MDI over successive child ages. By 36 months, 40% of the variance in Bayley MDI was accounted for by model estimates that included prior and current measures of parenting, family resources, and child development. Thus, although specific influences on children resulted in relatively small increments on cognitive achievement at any given age when single variables were considered, these small effects accumulated over time to explain a substantial portion of the variance in cognitive development by the time children reached age 3.

The present study should be interpreted in light of certain limitations. The measures of family resources that were considered do not reflect all dimensions of the stock of human capital in a family nor did analyses include all types of parenting behaviors. For instance, parents' time allocation and their goals for their children's achievement could influence both parenting quality and children's cognitive development. In addition, in constructing our measure of income per capita, we assumed that each member of the family receives an equal share of the family income. A better measure of the resources (including income) that the family allocates to the child would have been the expenditures of the family on child-specific goods (Meyer & Sullivan, 2003). However, this information was not available from our data. Researchers have found positive associations between expenditures on child-specific goods and cognitive development outcomes of infants from low-income and ethnically diverse backgrounds (Lugo-Gil, Yoshikawa, & Tamis-LeMonda, 2007). Moreover, the effect size of family resources on children's cognitive performance reported here is likely a low estimate given our sample characteristics. The current sample was restricted to low-income families, which resulted in a relatively narrow range of family resources compared to the population at large. It is therefore even notable that family resources still related to parenting quality at all ages after controlling for a range of child and parent characteristics. An important direction for future research would be to consider the joint influences of parenting behaviors and parents' expenditures on children's development outcomes in samples that include participants from a greater range of socioeconomic backgrounds.

Another potential limitation is the creation of composite scores of parenting quality at each age. Specifically, the measure of "parenting quality" is derived from free play interactions, the HOME, and a challenge task, and each of these measures in turn comprise multiple indicators. For example, mothers' positive regard, cognitive stimulation, and sensitivity were coded from the videotaped free play assessments and were combined into a composite of "supportiveness" following precedent as well as based on their high collinearity. On the positive side, the combination of parenting measures and tasks into composite scores that are based in multiple measures with strong reliability coefficients (as here) provides a more robust and comprehensive measurement of parenting than a single item. More practically, it would be unwieldy to present separate model solutions for the multiple indicators of parenting obtained in this study. Nonetheless, the decision to use composite measures precludes examination of whether certain aspects of parenting are more predictive of child outcomes than are others. Research on parenting reveals that different forms or aspects of parenting differentially predict children's developmental outcomes, supporting a specificity model of effects (e.g., Baumwell, Tamis-LeMonda, & Bornstein, 1997; Bornstein & Tamis-LeMonda, 2001; Bornstein, Tamis-LeMonda, & Haynes, 1999; Tamis-LeMonda et al., 2001). However, in the present study, models testing the separate scores of parenting did not vary from those yielded in the overall model. Therefore, we felt confident that the use of a parenting quality composite did not conceal differential contributions of individual items or tasks.

Another potential limitations is the use of Likert scales and categorical data for a number of variables included in models, including low birth weight (dichotomous variable) and mothers' own reading practices (Likert scale with responses that were not equidistant). Although these variables predicted parenting and/or child development, they may have underestimated effects given that categorical measures do not reflect the full range of variation obtained with interval data.

Additionally, in testing our conceptual model, we controlled for parents' ethnicity and race in models. Not shown is the finding that when associations were examined separately in White, Latino, and Black families, patterns of covariation among measures did not vary. However, despite general similarities of influence, parenting is clearly shaped by parents' "ethnotheories" or views about children's development and appropriate ways to parent. Parents from different cultural communities vary in their beliefs and practices, and these differences are evident in the daily routines and experiences of young children (Tamis-LeMonda, 2003; Weisner, 2002). Therefore, future research should attend to both similarities and differences in the nature and effects of socialization processes on children's developmental outcomes across different racial and ethnic populations.

Further studies are also needed on the processes that may determine family income, maternal educational achievement, and other family resources. Although focus here was on the ways that family resources might affect parenting and child development, it is also plausible that parenting behaviors and child development influence the amount of available resources in a family. Future research should consider multiple influences among parenting behaviors, children's development outcomes, and family resources within a framework in which the child is viewed as an investment that yields returns across the span of the child's lifetime (Brown & Flinn, 2006).

A final caveat of the current paper is that the statistical approach to modeling reciprocal influences between parenting quality and children's cognitive development did not fully account for simultaneity biases in our estimates. That is, although we analyzed reciprocal effects between parenting quality and child cognitive development outcomes, one could argue that these processes are determined at the same time. Evidence from level and change models of parenting quality and child cognitive development suggests that concerns about selection bias should not be critical. However, to fully address both the selection bias and the issue of simultaneity, we should develop and estimate a model of parents' behavior in which parenting quality and outcomes for children are determined simultaneously (Dahl & Lochner, 2005; NICHD Early Child Care Research Network & Duncan, 2003). This was beyond the scope of this article and it is a matter of consideration for future research.

We believe that our results have important policy implications in light of the finding that family income effects were relatively small and mediated by parenting quality. First, not unlike previous research in this area (Yeung et al., 2002), our results imply that programs aiming solely at supplementing family earnings may not have a strong impact on child cognitive development. In contrast, programs that offer a combination of cash assistance and services designed to improve the quality of parenting may be more effective in promoting cognitive development outcomes among low-income children during the important years that precede entry to school.

Second, our results support services focused on enhancing parents' resources beyond income alone. Strengthening the quality of parenting should also include services aimed at improving family literacy and education, reducing parental stress, and providing high-quality child care. Of all measures in the model, mothers' WJ scores were the strongest predictors of parenting and mothers' education strongly predicted both parenting quality and children's Bayley MDI scores.

In closing, the resources that parents bring to their families satisfy a number of needs in the family, one of them being support for the development of children. Thus, supplementing family income or providing parents with employment and child care services might not be enough to improve low – income children's development outcomes (Morris, Duncan, & Rodrigues, 2007). Children's participation in preschool education intervention programs and efforts to support positive parenting in low-income households are also vitally important to preparing children for later entry to school.

Notes

1. Detailed information on the instruments used in the EHS study, on how the data were collected, and on other studies based on the EHS database can be found in Administration of Children and Families, Office of Planning, Research, and Evaluation (2007) and Mathematica Policy Research Inc. (2007).
2. Among the children included in our sample (N = 2,089), those who had missing data on child outcomes (Bayley, 1993) were more likely to be male, to have mothers with lower levels of education and income at baseline, and to be living in the Midwest and less likely to be living in two-parent households. Mothers who had missing data on parenting quality at any age were more likely to be living alone at baseline, to be Black, to be less educated, to have lower income levels at baseline, and to be living in the Midwest. Participants who had missing data on income per capita were more likely to be mothers of firstborns, to be Black, to be living with their mother and other adults at baseline, to be younger, to have lower levels of education and income at baseline, and to be living in the Northeast and the Midwest.
3. The norming sample of the BSID – III was a national, stratified random sample of 1,700 children aged 1 – 42 months. For the MDI, the average Cronbach's alpha across age groups was .88 and interrater reliability was .96.
4. We also estimated alternative specifications of the model in which the three parenting constructs (supportiveness, quality of the home environment, and sensitivity and regard in challenge tasks) were included separately. We found that each parenting task/assessment contributes to children's cognitive development at 14, 24, and 36 months to a similar magnitude. In addition, these model specifications did not adjust to the data significantly better than the specification that used the parenting quality composite. Therefore, we concluded that the use of a parenting quality composite did not conceal differential contributions of the individual tasks. Results from estimations of alternative specifications of the model are available from the authors upon request.
5. Estimates of the disturbances of parenting quality and child outcomes, of the unanalyzed associations (or observed correlations) between the family resources variables, and of the paths between background factors and parenting are available from the authors upon request.
6. The reported statistical significance of the estimates of indirect effects presented in Table 8 is based on bootstrap standard errors, obtained from the bootstrap option available in MPlus.

Phonological and Semantic Priming in Children With Reading Disability

Rebecca S. Betjemann and Janice M. Keenan
University of Denver

Lexical priming was assessed in children with reading disability (RD) and in age-matched controls (M = 11.5 years), in visual and auditory lexical decision tasks. In the visual task, children with RD were found to have deficits in semantic (SHIP – BOAT), phonological/graphemic (GOAT – BOAT), and combined (FLOAT – BOAT) priming. The same pattern of semantic priming deficits also occurred in auditory lexical decisions, suggesting that the semantic deficits are not confined to reading. Children with RD also showed less priming than reading-age matched controls, suggesting that their priming deficits are not simply due to lower reading level but are due to the reading disability in particular. These semantic deficits may contribute to both the word reading and the comprehension problems seen in children with RD.

Early models of word recognition assumed that the process of identifying a word is completely independent of the process of retrieving a word's meaning (e.g., Forster, 1976). Much like finding the definition of a word in the dictionary only after one has mapped the spelling onto the dictionary entries, so too in these models, only after the correct lexical entry was identified was the semantic information available.

Current models of word recognition, such as the popular triangle model of Plaut, McClelland, Seidenberg, and Patterson (1996), however, consider semantics to also be a player in the identification of single words, along with orthographic and phonological representations. Even nonconnectionist models, such as more recent formulations of the dual-route model (Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001), include a semantic component that contributes to word identification. But despite such depictions, semantics has been, as Keenan and Betjemann (2007) recently termed it, the "neglected side of the triangle" in explanations of single-word reading. Semantics is typically invoked only to explain word identification when a word occurs in context. Also, when a child is found to have problems in word identification out of context, the problems are attributed only to deficits in phonological and orthographic processing, not semantics.

Keenan and Betjemann (2007) tried to counter this neglect by reviewing a number of studies that make a case for the involvement of semantics in single word identification both from a theoretical perspective and from empirical evidence. They contend that, at least in the English language, the case for semantic involvement is compelling. In English, orthographic and phonological pathways alone cannot efficiently master all the words because the mappings between these two domains are often inconsistent (so-called irregular words). In models including semantics, activation spreads from orthography and phonology to semantic representations, and these bidirectional connections with semantics facilitate word recognition and make the process more efficient. Thus, when semantic layers were added to connectionist models that initially only included orthography and phonology (Seidenberg & McClelland, 1989), the models were able to perform better on exception word learning, nonword pronunciation, and lexical decision (Plaut et al., 1996). Furthermore, a number of empirical studies show that although the contribution of semantics may not always be required for normal word identification, it is automatically activated nonetheless (Byrne & Shea, 1979; Forster & Hector, 2002; Meyer & Schvaneveldt, 1971; Seidenberg & Tanenhaus, 1979; Swinney, 1979).

If semantics is a significant contributor to word identification, it raises the question as to whether deficits in semantics may be contributing to word decoding problems in children with reading

---

This research was supported by grant NIH HD027802 to Janice M. Keenan through the Colorado Learning Disabilities Research Center. Rebecca S. Betjemann is now at the Institute for Behavioral Genetics at the University of Colorado and was supported in writing this article by NIMH training grant T32 MH016880-25 to J. Hewitt at the University of Colorado. We are grateful to all the participants and their families; to Dick Olson, John DeFries, and Sally Wadsworth for the word decoding and IQ scores on our participants; to Bruce Pennington and Erik Willcutt for the ADHD scores; to all the testers; and to Laura Roth and Amanda Miller for their comments on the manuscript.

disability (RD). RD is most typically associated with deficits in phonological and/or orthographic representations (Snowling, 2000; Wagner & Torgesen, 1987), not semantic representations; however, Vellutino Scanlon, and Spearing (1995) suggest that whereas phonological deficits may have the strongest influence on reading problems, deficits in semantics likely contribute to some extent, as well. More typically, semantic representations are thought to be a strength in children with RD because they rely more on semantic context to assist them in word identification. This is shown by studies that contrast word identification performance in context versus out of context. Children with RD show larger context effects than typical readers in terms of both speed and accuracy (Ben-Dror, Pollatsek, & Scarpati, 1991; Bruck, 1990; Nation & Snowling, 1998; Perfetti & Roth, 1981; Simpson & Lorsbach, 1987; Simpson, Lorsbach, & Whitehouse, 1983; Stanovich, 1980).

There are three reasons why this finding should not be interpreted as evidence that semantics is a strength for children with RD. One is that they rely more on context than children with normal reading skills because their decoding is weak and they need to use context to compensate. For example, some studies have used sentence primes, where the sentence context allows readers to predict possible target words that have meanings fitting that context. Poor readers who have difficulty reading the target words out of context may be more likely to strategically use the content of the sentence to guess what the word might be (Stanovich, 1980, 1984; see also Ashby, Rayner, & Clifton, 2005; Frost et al., 2005). Thus, improvement with context says more about these children's problems out of context than about their semantic representations.

The other two reasons why improvement in word identification with context should not be regarded as evidence for better semantic representations are measurement issues. Because children with RD read more slowly, they can show larger context effects than typical readers in terms of the size of the *absolute difference* between in- and out-of-context reading time. However, that difference is often eliminated when one controls for baseline differences in speed of responding (Chapman, Chapman, Curran, & Miller, 1994; Nation & Snowling, 1998; Tunmer & Chapman, 1998). Similarly, poor readers show greater improvement in accuracy of word identification when words occur in context than out of context because they identify fewer words correctly out of context than children with normal reading skill. Thus, whereas good readers are often already near ceiling in the out of context condition, children with RD have more room for improvement.

If poor readers' greater improvement in word identification does not imply that semantics is a strength for them, then it is possible that it could be a deficit. Semantic deficits in children with RD are not unreasonable to hypothesize because it makes sense that the same factors that produced weaker phonological and orthographic representations in these children could very well have also produced weaker semantic representations. Furthermore, because children with RD tend to read less than other children (e.g., Perfetti, Marron, & Foltz, 1996; Stanovich, 1986), they would also have less exposure to semantic information, which could further hinder the development of semantic representations and connections (Vellutino, Scanlon, & Tanzman, 1988; Vellutino et al., 1995).

Support for the possibility of deficits in semantic representations in children with RD comes from the finding that they show poor comprehension not just when they are reading but also when they are listening (e.g., Betjemann, Keenan, & Fazendeiro, 2002; Betjemann, Keenan, & Olson, 2003; Catts, Hogan, & Fey, 2003; Mann, Liberman, & Shankweiler, 1980; Mann, Shankweiler, & Smith, 1984; Spring & French, 1990; Tiu, Thompson, & Lewis, 2003). If the deficits in these children's lexical representations were simply in the mappings of orthography onto phonology, then when such mappings are not involved, as in listening, they should not show a deficit. The fact that they do show deficits in listening comprehension suggests that disabled readers may have broader deficits.

Beyond listening comprehension, there are other studies that suggest impoverished semantic processing using explicit measures. For example, studies have shown that poor readers have deficits on measures of semantic categorization and category recall (e.g., Ben-Dror, Bentin, & Frost, 1995; Bjorklund & Bernholtz, 1986; Lovrich, Cheng, Velting, & Kazmerski, 1997; Vellutino et al., 1995, 1998), measures of receptive and expressive semantic abilities (Purvis & Tannock, 1997), and measures of vocabulary (Assink, Soeteman, & Knuijt, 1999; Vargo, Grosser, & Spafford, 1995; Vellutino et al., 1995). Although these studies suggest that children with RD may have explicit semantic deficits in addition to their phonological deficits, it is unclear if these semantic deficits will be present with measures of implicit semantic processing, such as priming.

The purpose of the research presented here was to explore the deficits in the lexical representations of poor readers, including possible deficits in semantic representations, by examining priming in the lexical decision paradigm. Priming offers the advantage of assessing lexical representations implicitly. For example, in many assessments of phonological representations, such as phonological awareness tasks (e.g., Wagner & Torgesen, 1987), poor performance of children with RD due to deficits in their phonological representations is confounded with their ability to understand and respond to instructions that require explicit manipulation of the representations. In contrast, priming assesses lexical representations uncontaminated by these other factors.

The lexical decision task does not require children to read the words aloud. They simply press one button if the stimulus is a word and another if it is not. Thus, children with RD who might recognize a word but have difficulty pronouncing it are not penalized. In addition, by having children make lexical decisions rather than perform a naming task where they would read the words aloud, we can also examine priming in an auditory lexical decision task. Being able to do a comparison of performance across modalities is very important to determine the extent to which deficits are specific to reading. If any priming difficulties that children experience in the visual domain disappear when they are making the decision based on auditory stimuli, then we can conclude that the deficits are specific to reading. On the other hand, if similar priming deficits are present in both auditory and visual modalities, then it suggests the deficits are in the lexicon and not specific to reading.

Facilitation from priming is evaluated by determining if the time to process a target word is shorter following a related prime word than following an unrelated prime word. If so, the prime is said to have preactivated the target, and thus the target requires less processing to bring it to full activation and identification. Because the amount of facilitation provided by the prime is related to the similarity of prime–target representations, the amount of facilitation can be used to assess the quality of lexical representations and compare them across typical and disabled readers. If a child has deficiencies in their phonological or semantic representations, then we would expect that when the target word is presented, it will not overlap with the prime word as well as it does for children whose representations are not affected, and thus, they will show less facilitation from the prime.

Previous studies of priming in children with RD have often used sentences as primes (Ben-Dror, Pollatsek, & Scarpati, 1991; Bruck, 1990; Nation & Snowling, 1998). As described above, when sentences are used as primes, any differences found between children with RD and skilled readers could simply reflect differences in their use of strategy to predict the target from the prime, rather than differences in the quality of lexical representations. To investigate the quality of lexical representations uncontaminated by possible strategy differences, the current study uses single-word primes.

There have been only a handful of studies that have examined priming in poor readers using single-word primes. One was by Simpson et al. (1983) in which they investigated semantic priming in latencies to read the words aloud rather than to make lexical decisions. They found greater priming in the poor readers than in the good readers. However, it is difficult to interpret these results because they are not adjusted for differences between the groups in baseline response speed, so priming effects are confounded with group differences in speed and accuracy.

A study by Merrill, Sperber, and McCauley (1980) and a study by Assink, Van Bergen, Van Teeseling, and Knuijt (2004) both found no differences in semantic priming between above and below average readers with single-word primes. However, both studies had small sample sizes and thus recommended caution in interpreting their nonsignificant effects.

Booth, Perfetti, and MacWhinney (1999) also used single-word primes but their focus was to investigate phonological and orthographic priming in children with RD. They presented visual primes and targets for very fast, fixed durations for all children, and then the children were asked to write down the target word they saw. Although they found significant deficits in both orthographic and phonological priming in poor readers relative to good readers, there are at least two problems with conclusively interpreting their results as evidence for weaknesses in poor readers' lexical representations. One is that the duration of the prime may not have been sufficient for children with reading problems to identify it or process it fully, as better readers could. When the results showed less priming in poor readers, it could have been because on many trials the exposure was too short for children with RD to process the prime sufficiently. Furthermore, because children had to accurately spell their responses for them to be counted as correct, the results are confounded by spelling deficits that are often seen in children with RD (Snowling, 1998).

The current study attempts to improve on previous research in the following ways. As noted above, we use single-word primes rather than sentences to avoid possible confounds with strategy differences across groups. Second, we avoid the problems of children with RD possibly not identifying the prime by using a procedure called "active priming," which requires that the child make a lexical decision to the prime as well as to the target. Because the prime stays on the screen until the child makes a response, we can be sure that the prime is not presented too fast for the poor readers. Third, we adjust for differences between the poor readers and their controls in baseline speed of responding when we examine the amount of facilitation from related primes. Finally, we offer a broader assessment of lexical representations because we examine priming from multiple types of related primes as we will now explain.

As shown in Table 1, we examine priming from identity primes, phonologically/graphemically related primes, semantic primes that are synonyms, semantic primes that are associates, and what Keenan and colleagues (Keenan, 2000; Keenan, Grubb, & Betjemann, 1999; Keller, 1981) have termed *combined* primes. Combined primes are related to the target both semantically and phonologically/graphemically, such as WINE-DINE. Keenan and colleagues have consistently found that skilled readers' visual lexical decision times show more priming from combined primes than from single-dimension primes (Betjemann & Keenan, 2001; Keenan & Betjemann, 2001, 2002; Keenan et al., 1999; Keller, 1981). This suggests that information from both the semantic and phonological/graphemic similarity is activated and facilitates processing of the target (c.f. Gonnerman, Seidenberg, & Andersen, 2007). Combined primes thus represent a powerful tool for assessing priming in children with RD because if there is a deficit in a single-dimension priming condition such as semantic primes, then we can check the reliability of this finding by determining if it also shows up as a deficit in the combined condition. Thus, the combined prime condition functions as a replication of the single-dimension prime conditions and can provide additional information on potential deficits in children with RD.

The goal of this priming study then is to examine the nature of the lexical representations in children with RD compared to children with normal reading skills. If poor readers have less precise or less efficient semantic, phonological, or orthographic representations than their controls, it should show up as a priming deficit.

Priming deficits can be manifested in two ways. One is within the RD group itself; a priming deficit on a certain dimension would be evident if response time to that prime condition was not significantly different from that of the unrelated condition. Additionally, a priming deficit could be observed in the RD group relative to the control group; such between-group priming deficits would be shown by baseline-adjusted facilitations for a specific type of related prime being significantly less in the RD group compared to that of controls.

It is possible that there can be group differences between children with RD and controls not only on reading ability but also on IQ, vocabulary, and symptoms of attention deficit hyperactivity disorder (ADHD). Thus, we examine group differences on these variables, and then in our priming analyses, we examine whether these variables are related to group differences in priming between children with RD and their controls.

Experiment 1a: Visual Lexical Decision Task

Method

Participants. A sample of 280 twins and their siblings, ages 8–18, who were part of a larger study by the Colorado Learning Disabilities Research Center (CLDRC; DeFries et al. 1997; Olson, 2004) participated in the visual lexical decision task. Participants were identified from school records from 27 different local school districts. Children were invited to participate if they were identified by school records or parent report to have a school history of reading problems or ADHD, and a control group of twin pairs was also invited to participate. The overall sample was 48% male and 52% female. Similar to the local population, 92% of the sample was Caucasian, 4% Hispanic, and other groups made up 1% or less. Fifty-eight percent of the parents had a college education or higher.

From this sample, 78 children with RD were matched with 78 non-RD control children on chronological age (NRD-CA group). The children with RD were defined by their performance on the Timed

Table 1
Examples of Stimuli for Each Prime Condition

Prime condition	Prime – target		Prime – target		Prime – target		Prime – target	
Identity	BOAT	–BOAT	SHIRT	–SHIRT	BAKE	–BAKE	DAY	–DAY
Combined	FLOAT		SKIRT		CAKE		PAY	
Phonological/graphemic	GOAT		FLIRT		RAKE		BAY	
Semantic synonym	SHIP		BLOUSE		ROAST		DAWN	
Semantic associate	SAIL		PANTS		PIE		BIRTH	
Unrelated	YIELD		GLOW		LOSE		MENU	

Table 2

Participant Descriptives for Children With Reading Disability, Chronological-Age Matched Controls (NRD-CA), and Reading-Age Matched Controls (NRD-RA) in Experiments 1a, 1b, and 2

	Experiment 1a: Visual task		Experiment 1b: Visual task with reading-age match			Experiment 2: Auditory task	
	RD ($n = 78$)	NRD-CA ($n = 78$)	RD ($n = 42$)	NRD-RA ($n = 42$)	NRD-CA ($n = 42$)	RD ($n = 78$)	NRD-CA ($n = 78$)
Age	11.5	11.4	13.5	9.6	13.4	11.4	11.5
Decoding composite *z* score	−1.61	0.83	−1.66	0.71	0.78	−1.69	0.80
PIAT Word Recognition raw score			50.6	50.8	66.6		
WISC–R Full Scale IQ	104.7	115.9	103.9	115.5	115.5	103.3	117.1
WISC–R Vocabulary subtest standard score	10.3	12.8	10.0	12.7	12.7	10.0	13.1
ADHD symptoms mean (scale 0–3)	0.90	0.63	0.76	0.70	0.60	0.94	0.71

Note. PIAT = Peabody Individual Achievement Test; WISC–R = Wechsler Intelligence Scale for Children–Revised; ADHD = attention deficit hyperactivity disorder.

Word Recognition Test (Olson, Forsberg, Wise, & Rack, 1994) and the Peabody Individual Achievement Test, Word Recognition subtest (PIAT; Dunn & Markwardt, 1970). Participants were classified as RD if their composite of age-adjusted *z*-scores from the two word decoding tasks fell below −0.67 (lower 25%) and were classified as non-RD controls if their composite z score was above 0 (upper 50%). As shown in Table 2, the groups did not differ on age, $F(1, 154) < 1$, but the difference in their mean decoding z scores was highly significant, $F(1, 154) = 575.83$, $p < .001$. Participants in both groups had Wechsler Intelligence Scale for Children–Revised Full Scale IQ (WISC–R FSIQ; Wechsler, 1974) scores over 80 and had a high level of accuracy in the task (70% or higher correct on both critical trials and all trials). As shown in Table 2, there were group differences in IQ, $F(1, 154) = 45.2$, $p < .001$; oral vocabulary (WISC–R Vocabulary subtest; Wechsler, 1974), $F(1, 154) = 45.2$, $p < .001$); and symptoms of ADHD (parent and teacher report on the Disruptive Behavior Rating Scale; Barkley & Murphy, 1998), $F(1, 154) = 7.54$, $p < .01$. It was these differences that led us to investigate the relationship between priming and these factors, as well.

Materials. The stimuli consisted of 72 critical prime-target word–word pairs, 36 word–nonword pairs, and 36 nonword–nonword pairs, so that there were an equal number of word and pronounceable nonword targets. Each participant saw the same 72 critical target words; what varied across participants was which prime type preceded a particular target.

As shown in the examples in Table 1, there were six prime conditions: unrelated, phonological/graphemic (both phonologically and graphemically related to the target), semantic associate, semantic synonym, combined (both phonologically/graphemically *and* semantically related to the target), and identity primes. Each participant saw 12 primes from each of the six conditions. Assignment of targets to prime condition was counterbalanced across participants by having six different stimuli lists, with each list having a different group of 12 primes from each prime condition paired with the same 72 target words. The power of this design is that all targets are paired with all prime conditions equally across participants, rather than targets always being paired with a specific prime condition. Thus, any differences between individual target words in domains such as neighborhood size, frequency, or regularity should not affect any particular prime condition more than another because the targets are the same across all prime conditions.

All items were generated to meet a specific list of criteria.[1] The type of semantic relation between the combined primes and the targets was controlled so that half of the pairs in the combined condition were semantic synonyms and half were semantic associates. There were also 64 practice pairs, created to be similar to the critical stimuli.

Design. The design was a 2 (reading ability group: RD, NRD-CA) × 6 (prime condition: identity, combined, phonological/graphemic, semantic synonym, semantic associate, unrelated) factorial. Each participant received all six prime conditions, so prime condition was a within-subjects factor, and reading ability was a between-subjects factor. The dependent variables were errors in identifying the targets as words and reaction times (RTs) to targets on correct responses.

Procedure. The task was run using the computer program E-Prime Version 1.1. On each trial, a prime and target were presented. Each participant responded to a total of 208 trials in six blocks. The first two blocks of 24 trials each were practice trials. The last four blocks of 40 trials each contained the critical trials. In each of these blocks, the first 4 trials were practice items, and the next 36 trials were critical pairs or nonword target pairs. Critical and nonword stimuli pairs were presented in random order within those trials.

The stimuli were presented on the computer screen in black 18-point Courier New font, centered on a white screen background. The task requirements were identical for all trials, regardless of relationship between the prime and the target. At the start of each trial, there was a 500-ms fixation cross (+) shown at the center of the screen to alert the participant that the stimulus was coming. After the cross, the prime was presented at the same center location, and the participant was to decide whether it was a word or not by pressing *yes* or *no* keys labeled on the keyboard. As soon as they responded to the prime stimulus, the prime disappeared, and then a mask of Xs equal to the length of the prime word was immediately shown for 500 ms. At the offset of the mask, the target immediately appeared and stayed on until the participant responded as to whether it was a word. After the response to the target, there was then a 1,000-ms delay before the next trial began. After each block of trials, feedback on average response time and percent correct for that block of trials was presented on the screen. The entire task took about 20 min to complete.

Results

Target items were included in the analyses of RT only if the responses to both the prime and the target were correct. Outliers, defined as data points beyond 2 *SD* from each individual's mean response time for correct answers, and responses faster than 250 ms were removed, resulting in the removal of 508 trials (4.5%). Target *errors* were counted only on those trials for which the response to the prime was correct, and the removal of RT outliers from the errors resulted in the removal of 573 trials (5.1%). The analyses were conducted both treating subjects as the random factor and treating items as the random factor. Because the results were the same for each, to simplify the presentation, only the analyses treating subjects as the random factor are presented.

Overall RTs and errors to visual lexical decisions. Figure 1 presents the RT data for the visual lexical decision task. Not surprisingly, the children with RD took longer ($M = 811$ ms) to determine that a target is a word than their chronological-age matched controls ($M = 734$ ms), $F(1, 154) = 9.14, p < .01$. They also made more errors, 8.1% for RD versus 3.5% for controls, $F(1, 154) = 28.87$, $p < .001$. There was no evidence of a speed – accuracy trade-off because error rates were positively correlated with RTs (RD: $r = .27$; NRD-CA: $r = .14$), allowing us to therefore interpret the RT differences presented in Figure 1.

The RT data in Figure 1 showed a significant main effect of prime condition, $F(5, 770) = 21.7$, $p < .001$. Overall, the identity condition is the fastest in both groups, and the unrelated condition is slowest, and the related prime conditions fall between these two extremes. The Prime Condition × Reading Ability Group interaction was not significant, $F(5, 770) = 1.47$, $p > .05$.

The identity condition was included as a check on a possible ceiling on priming effects; specifically, if the combined condition ended up not significantly faster than the single-dimension phonological or semantic prime conditions, it was important to know if this was because the combined condition was at the ceiling of how fast an individual could respond. Because RT was significantly faster in the identity condition than in the combined condition in both groups: RD, $F(1, 77) = 9.0, p < .01$, and NRD-CA, $F(1, 77) = 5.78, p < .05$, we can conclude that the combined condition was not at

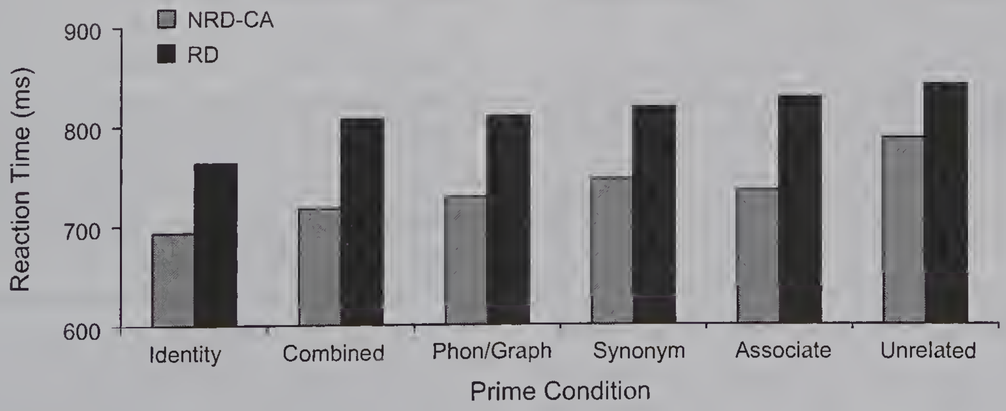

Figure 1. Reaction times in visual task, children with reading disability (RD), and controls (NRD-CA): Experiment 1a.

ceiling. Therefore, the remaining analyses did not include the identity condition.

RTs in the two semantic conditions, the synonym and associate conditions, were not significantly different from one another: RD, $F(1, 77) < 1$, and NRD: $F(1, 11) = 1.73$, $p > .05$. Because combined primes consisted of half semantic synonyms and half semantic associates, we used a mean of these two semantic conditions to compare semantic priming to the other conditions in the analyses of facilitation.

Facilitation from related primes. Facilitation from a related prime occurs if the RT to a target is significantly faster when it is preceded by a related prime than when it is preceded by an unrelated prime. Table 3 presents facilitation values computed as the difference between the mean RT of each prime condition and the mean of the unrelated condition.

For the control group, we found that each of the three related prime types provided significant facilitation in responding to the target. The controls showed significant facilitation in making a lexical decision about a target when it was preceded by a prime that was phonologically/graphemically similar, $F(1, 77) = 28.19$, $p < .001$, or semantically similar, $F(1, 77) = 34.4$, $p < .001$, or similar on both dimensions, combined, $F(1, 77) = 32.06$, $p < .001$. Furthermore, as shown in Table 3, the control group shows a pattern of greater facilitation from a combined prime that activates both semantic and phonological/graphemic dimensions than from either of the single-dimension primes.

The children with RD, like the controls, also showed significant facilitation in the time it takes to classify a target as a word when it was preceded by a word that was phonologically/graphemically related to the target, $F(1, 77) = 5.16$, $p < .05$. Thus, despite their reputed deficits in phonological and orthographic representations, the phonological/graphemic prime activates sufficient lexical information to preactivate related targets and thus producing significant facilitation from the similarity of the prime to the target on these dimensions. The children with RD also show significant facilitation when the prime is from the combined condition, $F(1, 77) = 5.37$, $p < .05$. However, unlike the controls, they do not show significant facilitation when the prime is only related to the target on a semantic dimension, $F(1, 77) = 2.53$, $p = .12$.

In order to directly compare priming between the groups, we need to accommodate the fact that the RD group is overall significantly slower. Chapman et al. (1994) recommend using baseline-adjusted facilitation values. These were computed for each participant in each prime condition by dividing raw facilitation by the participant's mean response time in all word target trials ([unrelated RT – related RT]/mean RT). The RD group showed significantly less facilitation than the NRD-CA control group across each prime condition: combined, $F(1, 154) = 6.43$, $p < .05$; phonological/graphemic, $F(1, 154) = 4.58$, $p < .05$; and semantic, $F(1, 154) = 6.01$, $p < .05$. Also, in contrast to the control group, who showed a tendency to get more facilitation from a combined prime than from a single-dimension prime, the children with RD show no more facilitation from the combined prime than from the phonological/graphemic prime, $F(1, 77) < 1$.

Because there were differences between the RD and the NRD groups in IQ, vocabulary, and symptoms of ADHD, we investigated if these were accounting for the group differences in priming. We computed correlations between baseline-adjusted facilitation in each prime condition with the IQ, vocabulary, and ADHD variables, and found that the correlations were all very low, ranging from −.004 to .16. None of the correlations were significant at the $p < .05$ level, and therefore, when we included these variables as covariates in the analysis, we found that none of the three covariates were significant, as would be expected: FSIQ, $F(1, 151) < 1$; vocabulary, $F(1, 151) < 1$; and ADHD, $F(1, 151) < 1$. Thus, despite overall group differences in these three variables, they are not significantly related to priming, and we therefore present the results without the covariates from here forward.

Table 3
Reaction time Facilitation (ms) in Visual Lexical Decision in Children With Reading Disability (RD) and Controls (NRD-CA): Experiment 1a

	Facilitation		Baseline-adjusted facilitation (facilitation/mean RT)	
	RD	NRD-CA	RD	NRD-CA
Combined (FLOAT – BOAT)	33.8	69.6	0.041	0.097
Phonological/ graphemic (GOAT – BOAT)	31.4	59.2	0.036	0.081
Semantic (SHIP – BOAT)	17.8	46.9	0.022	0.063

Although implicit tasks are believed to be minimally sensitive to strategic responding, over the course of the experiment, participants could potentially adopt strategies that might change the way they respond. These strategy differences could affect one type of prime relationship more than another, or one group of participants more than another; therefore, it is important to rule out the possibility that this is driving our results. We assessed strategy changes over time by examining the patterns of priming in the first and second halves of the experiment. Although the overall response times do get faster in the second half of critical trials compared to the first half, $F(1, 149) = 16.85$, $p < .001$, there is not a significant interaction between experiment half and prime condition, $F(2, 300) < 1$, nor is there a three-way interaction among reading group, half, and prime condition, $F(2, 300) < 1$.

Discussion

Our results show that children with RD get less facilitation from related primes, regardless of the type of relatedness, than their age-matched controls. Because children with RD are known to have problems with phonological processing, less priming than controls in the phonological/graphemic condition is not surprising. What is noteworthy, however, is that they are also showing deficits in semantic priming. Not only are they showing deficits in priming relative to the controls, but they also do not even show significant facilitation from semantic primes compared to the unrelated condition. This semantic priming deficit is also reflected in the combined priming condition; for children with RD, the combined priming condition offers no more facilitation than the phonological/graphemic prime by itself, suggesting that for them, the semantic dimension is not significantly activated in the combined primes.

These priming deficits raise the question of what underlies them. The priming differences are not simply due to IQ, oral vocabulary, or ADHD because these measures are not significantly correlated with priming. So, what is it about the lexical representations and connections in the children with RD that is causing these differences? It is important to remember that the RT differences we observed are all on items that the children got correct. In other words, they are occurring on words that the children know, so the deficits in priming cannot simply be attributed to lack of lexical representations. However, it could be that even though they know the words, the children with RD might not know them as well as the controls because they do after all have a lower reading level. Thus, we turn next to consider whether the differences we observed might be due to their reading level.

If the priming deficits that we observed are due to a developmental delay in the RD group, that is, due to their lower reading level, then if we match them to younger children who have the same reading level but who do not have a reading disability, the differences in performance should go away. On the other hand, if the priming deficits that we observed are due to qualitative differences in the children's representations as a function of their having a reading disability, and not just due to lower reading level, then we might expect that our children with RD would continue to show priming deficits even relative to younger children who have the same reading age. Experiment 1b examines this question by comparing a group of children with RD to both a group of reading-age matched children (NRD-RA) and a chronological-age matched NRD-CA group.

Experiment 1b: Visual Lexical Decision Task With Reading-Age Matched Controls

Method

The requirement of having to derive two different control groups from our pool of participants, one matched on age and one matched on reading level, meant that some of the younger RD children from Experiment 1a could not be included in these analyses because their reading ages were so low that they would have required reading age controls much younger than any of the children in our sample. Thus, three new groups were chosen from the pool of 280 children who had participated in the visual lexical decision task described above. The groups for Experiment 1b were smaller than those for Experiment 1a, with only 42 participants per group, and the RD and NRD-CA participants were over 2 years older than in Experiment 1a. The participants with RD were matched to NRD participants on reading age (NRD-RA) as measured by their raw score on the PIAT Word Recognition subtest (Dunn & Markwardt, 1970), and matched to NRD-CA participants on chronological age. Descriptive statistics on the three groups are presented in the middle column of Table 2. The RD and NRD-RA groups were not different on reading age, $F(1, 82) < 1$, and the RD and NRD-CA groups did not differ in chronological age, $F(1, 82) < 1$. The age-adjusted decoding composite scores of the two control groups, NRD-CA and NRD-RA, did not differ, $F(1, 82) < 1$.

Results and Discussion

Overall error rates did not differ across the three groups, $F(2, 123) = 2.17$, $p > .10$. Errors were positively correlated with RTs ($r = .15$, $N = 756$, $p < .001$), indicating no speed – accuracy trade-off.

The RTs to make correct visual lexical decisions on targets are presented in Figure 2. This figure shows that for every prime condition, the NRD-CA group was the fastest, the children with RD were the next fastest, and the younger children with the same reading age as the children with RD were the slowest to make their lexical decisions. A 3 (reading ability group) × 6 (prime condition) repeated measures analysis of variance showed a significant main effect of reading ability group, $F(2, 123) = 19.66$, $p < .001$; planned comparisons showed that the NRD-CA group ($M = 643$) was significantly faster than the RD group ($M = 703.2$), difference $F(1, 82) = 4.69$, $p < .05$, and the RD group was significantly faster than the younger NRD-RA group ($M = 815.4$), difference $F(1, 82) = 15.2$, $p < .001$.

These differences in overall speed of response necessitate that we examine any group differences there might be in facilitation from related primes by examining baseline-adjusted facilitation, as we did in Experiment 1a. These values are shown in Table 4. Because of the smaller sample size, group differences in facilitation were evaluated collapsed across prime types. Figure 3 shows the baseline-adjusted facilitations for each of the three groups. Even with the smaller sample sizes of this experiment, an interesting pattern of group differences is evident. Specifically, the NRD-CA and NRD-RA groups show very similar amounts of facilitation (NRD-CA: $M = .071$; NRD-RA: $M = .070$, difference $F(1, 82) < 1$, and much greater facilitation than that shown by the RD group ($M = .029$). Therefore, even though the NRD-RA group is much younger, and they responded more slowly to the targets, the proportional amount of facilitation they show from having the target preceded by a related prime is very similar to that of the older controls. However, this is not true of the children with RD. They showed less facilitation than either of the control groups: RD versus NRD-CA, $F(1, 82) = 5.14$, $p < .05$, and RD versus NRD-RA, $F(1, 82) = 3.09$, $p = .08$. The children with RD have the same reading level as the NRD-RA children, and they are almost 4 years older, and yet they are showing reduced priming. This shows that the priming deficits in RD are due to the disability per se, not their reading level. It suggests that there are deficiencies in their lexical representations or networks that limit the facilitation from the prime that even younger children's lexical representations provide.

Finding that priming deficits in RD are due to the disability per se, and not reading level, raises the question of whether priming deficits would also be observed outside the domain of reading. It is reasonable to think that the deficits might be confined to reading. Children with RD have weak orthographic – phonological mappings (Snowling, 2000), and because reading invokes these weak mappings, it could be that the weak orthographic – phonological mappings slow down the whole network and result in reduced priming across the board when reading. If that is the case, then if we have children with RD simply listen to words and make auditory lexical decisions, they should no longer show priming deficits. On the other hand, if the deficits in lexical representations are broader than weak orthographic – phonological mappings, then we might expect to see priming deficits even when reading is not required; that is, the children with RD should show priming deficits in auditory lexical decisions just like they did in the visual lexical decisions. The next experiment uses auditory lexical decision to answer this question.

Table 4

Reaction time (RT) Facilitation (ms) in Visual Lexical Decision in Children With Reading Disability (RD), Reading-Age Matched Controls (NRD-RA), and Chronological-Age Matched Controls (NRD-CA): Experiment 1b

	Facilitation			Baseline-adjusted facilitation (facilitation/mean RT)		
	RD	NRD-RA	NRD-CA	RD	NRD-RA	NRD-CA
Combined (FLOAT – BOAT)	24.1	71.9	23.1	0.034	0.090	0.084
Phonological/graphemic (GOAT – BOAT)	16.5	55.4	43.8	0.022	0.069	0.071
Semantic (SHIP – BOAT)	23.1	45.5	36.8	0.032	0.052	0.058

Experiment 2: Auditory Lexical Decision Task

Method

Participants. A new group of 276 participants, who were also participating in the larger CLDRC study, participated in the auditory lexical decision task. From these, a group of 78 children with RD and 78 without RD (NRD-CA group) were selected using the same criteria described in Experiment 1a. As shown in Table 2, the mean ages of the two groups were not significantly different, $F(1, 154) < 1$, but the RD group was significantly impaired compared to the NRD-CA group on word decoding, $F(1, 94) = 656.91$, $p < .001$, as well as on IQ, $F(1, 154) = 67.2$, $p < .001$; WISC vocabulary, $F(1, 154) = 66.8$, $p < .001$; and ADHD symptoms, $F(1, 154) = 4.94$, $p < .05$. We matched the RD and NRD-CA participants in the auditory lexical decision to the participants from these groups in the visual lexical decision task of Experiment 1a; they were matched on both decoding ability and chronological age so that we could do comparisons across modalities.

Materials. Digitally recorded critical word stimuli from the visual task were used in this auditory task.[2]

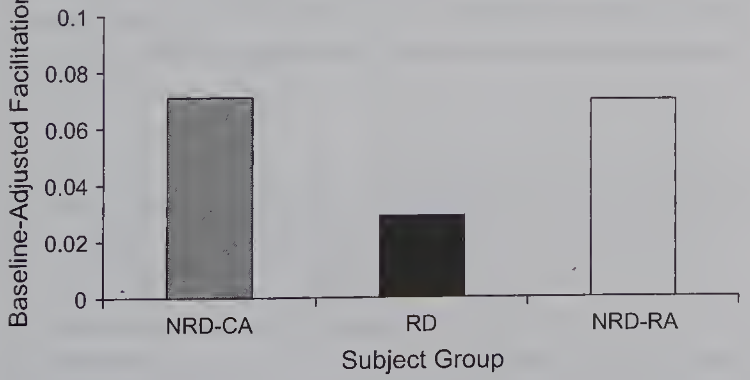

Figure 3. Mean baseline-adjusted facilitation in visual task, children with reading disability (RD), reading-age matched controls (NRD-RA), and chronological-age matched controls (NRD-CA): Experiment 1b.

Design. The design of this experiment is the same as was described in Experiment 1.

Procedure. The procedure in this task was the same as in the visual task in Experiment 1, except for a few differences due to the different modality of presentation. In this task, the stimuli were recorded into digital audio sound files and were played for the participants through headphones. Piloting showed that the children were most attentive if at the start of each trial, an alerting tone was played while simultaneously showing a fixation cross (+) at the center of the screen, that is, giving the child something to look at signaling the imminent occurrence of the prime and target over the headphones. The procedure on each trial thus involved playing an alerting tone at the beginning with the fixation cross on the screen, then after a 500-ms delay, the prime was played; once the child pressed a button signaling whether the sound corresponding to the prime was either a real word or a nonword, then there was a period of 500 ms of silence with a blank screen, and then the target was played and the child pressed a button for the lexical decision on the target. Feedback was given at the same intervals, following the same procedure, as in the visual lexical decision, and was presented visually on the screen.

Results

Overall RTs and errors to auditory lexical decisions. Data were trimmed as described in Experiment 1a, resulting in the removal of outliers in 3.8% of the trials for the RT analyses and 2.9% of the trials in the errors analyses. Figure 4 shows the auditory lexical decision times for the six prime conditions in the RD and NRD-CA groups. Although this was a listening task, not a reading task, the children with RD were nonetheless significantly slower (M =1,190 ms) than the control group (M = 1,096 ms) to determine that the targets that they heard were

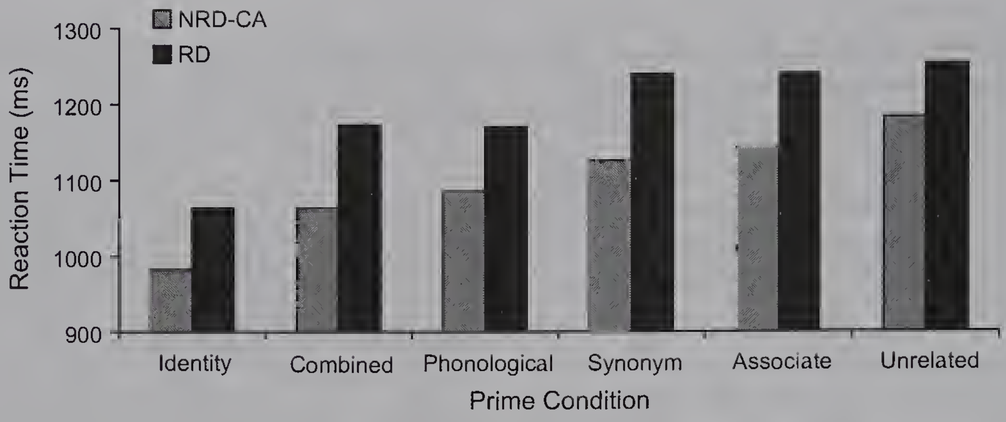

Figure 4. Reaction times in auditory task, children with reading disability (RD), and controls (NRD-CA): Experiment 2.

words, $F(1, 154) = 8.25$, $p < .01$; there was no significant interaction with prime condition $F(5, 770) = 1.11$. The RD group also made significantly more errors on the word targets than the NRD-CA group, 8.4% versus 4.8%; $F(1, 154) = 9.70$, $p < .01$, and again no significant interaction with prime condition, $F(5, 770) < 1$. Error rates and RTs for each prime condition were positively correlated (RD: $r = .25$; NRD-CA: $r = .26$), suggesting no evidence of a speed-accuracy trade-off.

The auditory lexical decision times in Figure 4 also show a significant main effect of prime condition, $F(5, 770) = 77.79$, $p < .001$. Furthermore, it looks very similar to that of the visual lexical decision RTs in Figure 1, in that for both, the identity condition was the fastest and the unrelated condition was the slowest. As in the visual task, we again found that RT in the identity condition was significantly faster than that in the combined condition in both groups: RD, $F(1, 77) = 27.52$, $p < .001$, and NRD-CA, $F(1, 77) = 35.79$, $p < .001$, showing that the combined condition was not at ceiling. RTs in the synonym and associate conditions were not significantly different from one another: RD, $F(1, 77) < 1$ and NRD, $F(1, 77) = 1.91$, $p > .05$; therefore, the semantic mean was used in the analyses of facilitation from related primes.

Facilitation from related primes. Table 5 presents facilitation values computed as the difference in the mean RT of each related prime condition compared to the mean of the unrelated condition. Just as we found in the visual lexical decision task, for the control group, each of the three related prime types provided significant facilitation in responding to the target. The controls showed significantly facilitated RTs to make a lexical decision about an auditory target when it was preceded by a prime that was phonologically similar, $F(1, 77) = 49.07$, $p < .001$, or semantically similar, $F(1, 77) = 16.16$, $p < .001$, or similar on both dimensions (combined), $F(1, 77) = 68.76$, $p < .001$.

The children with RD also showed significant phonological priming, $F(1, 77) = 24.57$, $p < .001$. However, in contrast to the control group, they did not show significant semantic facilitation, $F(1, 77) < 1$. Finding a semantic deficit in the RD group in making auditory lexical decision just like we found in the visual lexical decision suggests that the semantic deficit is not something that only happens when they are reading and invoking weak orthographic–phonological mappings. Instead, it appears rather robust and indicative of qualitative differences in their lexical representations.

Because the RD group had longer RTs than the NRD-CA group, we again computed baseline-adjusted facilitation values for the three prime conditions, as described in Experiment 1a. As in the visual modality, IQ, vocabulary, and ADHD symptoms were not correlated with facilitation (*r*s from −.12 to .07) and

Table 5
Reaction time (RT) Facilitation (ms) in Auditory Lexical Decision in Children With Reading Disability (RD) and Controls (NRD-CA): Experiment 2

	Facilitation		Baseline-adjusted facilitation (facilitation/mean RT)	
	RD	NRD-CA	RD	NRD-CA
Combined (FLOAT–BOAT)	78.1	117.9	0.078	0.109
Phonological (GOAT–BOAT)	81.0	95.4	0.075	0.088
Semantic (SHIP–BOAT)	11.7	46.7	0.019	0.046

were not significant as covariates in the analysis: FSIQ, $F(1, 151) < 1$; vocabulary, $F(1, 151) < 1$; and ADHD, $F(1, 151) < 1$. Although the main effect of subject group did not reach significance, $F(1, 154) = 2.19$, $p = .14$; nonetheless, for the semantic condition, the difference between the RD and NRD-CA groups was marginally significant, $F(1, 154) = 2.85$, $p = .09$.

Similar to what we found with the visual task, in this auditory task, the adjusted facilitation in the combined condition for the NRD-CA group is greater than that in the single-dimension phonological condition, $F(1, 154) = 3.22$, $p = .07$, suggesting that control children are getting some benefit from both the semantic and phonological dimensions in the combined primes. In the RD group, however, the combined facilitation is almost identical to the phonological facilitation, $F(1, 154) < 1$, suggesting that the children with RD are getting facilitation only from the phonological relatedness of the combined primes and not any additional benefit from the semantic relatedness.

Discussion

The goal of this experiment was to determine if the priming deficits that we observed in children with RD on the visual lexical decision task would still occur when the children did not have to read the stimuli but instead just listened to them. The view that the deficit in lexical representations in children with RD is only evident when they read predicts that when they are not reading and are just listening to make their judgments, they should do as well as controls. However, this did not happen. Lexical decisions were less accurate and took longer in the children with RD, even though the task did not involve reading.

Even on the words that the children with RD knew and made correct decisions on, they again showed no semantic priming, in contrast to the controls. In addition, the amount of priming they showed from a prime that combined both phonological and semantic priming was no greater for these children than from a prime that was only phonological, providing further corroboration that they were getting no benefit from the semantic relatedness of those primes. Thus, we can conclude that the lack of semantic priming that we observed in children with RD when they were doing the visual lexical decision task of Experiment 1 was not just a function of the task requiring reading. It suggests that there may be differences within the semantic representations themselves that lead to semantic deficits even in a non-reading task.

We did not see a significant deficit in the RD group in phonological facilitation in this auditory task, as we had seen in the visual task. The difference in phonological priming deficits between the two modalities could be due to the specificity of the deficits in children with RD. The difference between the auditory and the visual lexical decision tasks in the phonological priming condition is that in the visual task the child must first map the graphemes onto the phonemes in order to benefit from the phonological similarity between the prime and the target. Our finding that children with RD show phonological priming deficits in the visual task and not in the auditory task would suggest that these deficits on the visual task may reflect problems in the connections between phonology and orthography rather than within the phonological representations themselves.

Significant phonological priming in children with RD might seem surprising because they are known to have problems with explicit phonological processing (Snowling, 2000; Wagner & Torgesen, 1987), and there is evidence of implicit phonological processing deficits as well (Boada & Pennington, 2006). It should be noted that in our stimuli, the phonological primes rhyme with the targets; that is, the phonological similarity of the prime and target is in the rime of the word, and the onsets are different. This similarity in rhyme is very apparent in the auditory modality, and the patterns of phonological priming that we observed suggest that it was very apparent to children with RD as well as to controls. Our suggestion that rhyme-based priming could be contributing to our failure to find phonological deficits in the auditory task is consistent with that of other studies that show that, by fourth grade, children with RD are often doing almost as well as controls on rhyming tasks (Bowey, Cain, & Ryan, 1992; Bradley & Bryant, 1978). This also fits with Ziegler and Goswami's (2005) notion that during development, the grain size of the phonological representations shifts from larger to smaller: from units the size of words, to onset rimes, to individual phonemes. Although children with RD are slower at developing the smaller grain sizes, their phonological representations at the onset-rime grain size appear to be adequate enough so as to not show a difference in phonological priming compared to the control group with auditory presentation.

Modality Comparisons

We purposely selected the children for the auditory lexical decision task so that they were matched with the RD and NRD-CA participants in the visual task on both chronological age and reading ability, in order that we could do an analysis with modality as a between-subjects factor to assess the differences between the modalities. As shown in Table 2, there were no significant differences between the four groups of subjects in age, $F(3, 308) < 1$. The differences in decoding composite scores between modalities, within reading groups, were also not significant: RD, $F(1, 154) < 1$, NRD-CA and $F(1, 154) < 1$.

Overall RT was slower in the auditory task than in the visual task, $F(1, 310) = 309.56$, $p < .001$. This difference was expected because RTs are measured from the onset of the target. In the auditory task that includes the time it takes to present the target, which in contrast to the visual presentation, is not simultaneous but rather extended over time. This difference in baseline RTs across modalities required that we compare priming across modalities by using baseline-adjusted facilitation scores. It should be noted that by adjusting for baseline differences in modality, the main effect of modality is eliminated, $F(1, 301) = 1.17$.

The view that the deficit in RD only manifests in reading would predict significant interactions between subject group and modality. However, as we have already seen from the results of Experiments 1a and 2, the patterns of priming across the modalities were quite similar. This was confirmed by finding in this analysis that there were no significant interactions between modality and subject group, either overall, $F(1, 308) < 1$, or with prime condition, Prime Condition × Subject Group × Modality interaction, $F(2, 616) < 1$. The RD group showed less overall facilitation than the controls, $F(1, 308) = 8.92$, $p < .01$, and less facilitation in each prime condition: combined, $F(1, 308) = 8.12$, $p < .01$; phonological/graphemic, $F(1, 308) = 4.35$, $p < .05$; and semantic, $F(1, 308) = 8.59$, $p < .01$, but this did not differ across modality, further supporting the argument that priming deficits in children with RD are not confined to reading.

The only significant interaction with modality was that between prime condition and modality, $F(2, 616) = 5.74$, $p < .01$); it reflects a trend for the phonological and for the combined facilitation to be higher in the auditory task than in the visual task: combined, $F(1, 308) = 2.69$, $p = .10$, and phonological/graphemic, $F(1, 308) = 2.92$, $p < .10$. As noted earlier, this is likely due to the phonological rhyming relationship that is more apparent in the auditory task. Note, however, that there is no modality difference in semantic facilitation, $F(1, 308) < 1$.

General Discussion

The goal of this study was to assess the quality of the lexical representations in children with RD by determining whether they show deficits in priming in lexical decision tasks. We looked not only at phonological/graphemic representations, which are usually the focus of research on children with RD, but also at semantics, a somewhat neglected area in reading disability research (Keenan & Betjemann, 2007). We also assessed priming using combined primes that were related to the targets on both phonological and semantic dimensions, as a replication of the single-dimension prime conditions.

We found an overall priming deficit in the children with RD, and a consistent pattern of semantic priming deficits, in particular. The children with RD did not show significant facilitation compared to the unrelated condition with semantic primes, and they showed deficits in baseline-adjusted semantic facilitation compared to control children. These patterns were apparent in the combined prime condition, as well.

The semantic priming deficit occurred not only in the visual priming task but also in the auditory modality where no reading was required. Finding this deficit in both modalities suggests that the impairments in children with RD extend beyond those directly resulting from the mapping of orthography to phonology or beyond simply a lack of resources for processing when there is a strain on this system by having to decode the words (Perfetti, 1985). Instead, the findings in the auditory task suggest that there is a broader deficit. This deficit could be due to either slowness in activation of the semantic representations (e.g., Shanahan et al., 2006) or deficits in the organization within those representations. Although we cannot distinguish these causes in the current study, either leads to less efficiency overall in the semantic system.

We investigated whether the priming deficits shown by children with RD were just due to their lower reading level by comparing their performance to that of a group of children who were matched to them on reading age. We found that even though the reading-age matched control group was on average 4 years younger than the children with RD and slower to make their lexical decisions, they showed greater priming than the children with RD and comparable priming to the chronological-age matched controls. Hence, the priming deficits observed in the children with RD appear to be due to qualitative differences in activation of their representations stemming from their reading disability in particular and not just their lower reading level.

Priming deficits could be due to general slowing related to IQ, impaired executive functions related to ADHD, or having weaker vocabularies. Because vocabulary could be thought of as an explicit measure of semantics (e.g., Vellutino et al., 1995), one might expect that this measure in particular could be responsible for group differences in semantic priming. Like other researchers, we did find significant group differences in these variables (e.g., Pennington, 2006; Stanovich, 2000; Vellutino et al., 1995; Willcutt, Pennington, Olson, Chhabildas, & Hulslander, 2005). However, despite these group differences, we did not find that vocabulary was significantly correlated with baseline-adjusted facilitation in any prime condition, nor were IQ or ADHD symptoms significantly correlated with priming, after adjusting for baseline. This suggests that the priming task was picking up on some unique aspects of lexical and semantic processing that are impaired in the children with reading problems, beyond those that are measured explicitly by vocabulary and IQ. What might those deficits be? Priming deficits likely reflect impaired efficiency of the semantic network, including slower activation of semantics due to the strength of weights of the connections from phonology and orthography or slower settling of semantics because of less efficient coding of semantic representations. Vocabulary and most IQ subtests are not speeded; thus, even though they measure semantic knowledge, they do not account for deficits that are more specific to *efficiency* of semantic processing.

The semantic deficits we found in this study can help explain why many children with RD have comprehension problems not only when they are reading but also when they are listening (Betjemann et al., 2003; Catts et al., 2003; Mann et al., 1980, 1984; Spring & French, 1990; Tiu et al., 2003). Good comprehension requires that the meanings of words presented in a discourse are quickly activated, and they in turn quickly activate related concepts from long-term memory, so that all this semantic information can be easily integrated together into a coherent understanding (Kintsch, 1988, 1998). The semantic deficits observed in this study would slow down that activation and integration, and require more effortful processing for comprehension. Nation and Snowling (1999) found that semantic priming deficits are related to comprehension problems in nondisabled readers; our results suggest that this would apply in children with RD, as well.

In sum, the priming deficits observed in this study show that the problems in children with RD are not restricted to weaknesses in phonological representations and deficits in orthographic-phonological mappings (Snowling, 2000) but extend also into semantics. Our finding that these children show deficits not only when reading words but also when hearing them also supports the notion that their deficit is broader than is typically characterized. The breadth of the deficit can explain why children with reading problems show deficits in listening comprehension as well as in reading comprehension. We hope that these insights into the lexical representations of children with RD can help guide future research on early prevention and remediation, so that we can know best how to keep them from falling further behind.

Notes

1. Items met the following guidelines (from Keller, 1981). (a) Words were restricted to "relatively common" English words, although no minimum frequency of usage was specified. (b) Words with prominent or preferred single pronunciations were required so that phonemic similarity could be specified. (c) Although at least one word of nine letters in length was allowed, shorter words were preferred. (d) Proper names, contractions, and abbreviations were excluded. (e) Rhyming words (phonological/graphemic and combined) were required to share common orthography, so that they would be both phonemically and graphemically related. Hence, pairs such as WEIGHT–LATE and RARE–PAIR were not used. (f) Word pairings could not result from simple prefix substitution (e.g., INCREASE–DECREASE). (g) The separation of compound words into component words for prime–target pairs was avoided where possible (e.g., BACKTRACK into BACK–TRACK). (h) Unrelated primes were chosen randomly from other prime type stimuli lists as much as possible with the provision that no apparent relationship existed within a pair.
2. Two critical prime words were changed for the auditory task because of low frequency. One target word and its six prime words were also changed for this task. Most of the nonword stimuli were the same; the nonwords were originally developed for use with visual presentation, but then in piloting, some were harder to distinguish from real words in auditory presentation; therefore, a total of 38 of 108 critical-block nonword stimuli were modified for this auditory version.

Individual Differences in Adolescents' Beliefs About the Legitimacy of Parental Authority and Their Own Obligation to Obey: A Longitudinal Investigation

Nancy Darling
Oberlin College

Patricio Cumsille and M. Loreto Martínez
Pontificia Universidad Católica de Chile

Adolescents' beliefs about the legitimacy of parental authority and obligation to obey were examined in 568 Chilean adolescents (11–14 years old at Wave 1), followed once a year for 4 years. Adolescents' beliefs about parental legitimacy and obligation to obey declined with age. The steepest decline occurred during early adolescence, particularly in the personal domain. Adolescents who were uninvolved in problem behavior and perceived their parents to be supportive or high in monitoring at Wave 1 were more likely to endorse parental legitimacy and obligation to obey over time. There was little evidence that parenting or problem behavior moderated the normative decline in adolescents' beliefs about parental authority. Findings concerning individual differences in adolescents' endorsement of parental authority are highlighted in this study.

When parents set rules that adolescents disagree with, adolescents usually obey (Darling, Cumsille, & Martínez, 2007; Darling, Cumsille, & Peña-Alampay, 2005). Why? Most research on adolescent socialization has focused on what parents do to facilitate positive adolescent development (Parke & Buriel, 1998), with extensive literatures concerning both stylistic differences in parents' characteristics, such as support, and behavioral and psychological control (e.g., Barber, Stolz, & Olsen, 2005; Pettit, Laird, Dodge, Bates, & Criss, 2001), and on specific parenting practices such as monitoring (e.g., Crouter & Head, 2002). Although developmental researchers have long recognized that effective parenting is made easier with a cooperative child (Thomas & Chess, 1968), relatively less attention has been given to the processes underlying differences in adolescents' willingness to be socialized (although see Kerr, Stattin, & Trost, 1999; Moffitt, 1993; Patterson, DeBaryshe, & Ramsey, 1989, for important exceptions). Understanding these processes is particularly important during adolescence, when normative increases in adolescents' desire for psychological and behavioral autonomy are likely to conflict with continued parental efforts to protect, socialize, and regulate their children (Smetana, 2002). This article examines normative change and individual differences in adolescents' beliefs that parents have the right to set rules about particular areas of their lives (the legitimacy of parental authority) and their beliefs that they must obey parental rules they disagree with (obligation to obey). Both characteristics of adolescents and of their parents are examined as predictors of individual differences in adolescents' beliefs and as moderators of normative change.

Parents' knowledge of their adolescent children's lives, adolescents' decisions to share information about their lives, and adolescents' decisions to obey parents when they disagree with them depend in part upon adolescents' beliefs about the legitimacy of parental authority and their own obligation to obey. Legitimacy of parental authority refers to the extent to which parents' assertion of control over an area is believed to be a natural or an appropriate extension of their role as parents (e.g., Smetana, 1988). Obligation to obey is a related construct, referring to the belief that children are obliged to obey parents, even when they and their parents disagree. Darling and Steinberg (1993) hypothesized that one reason that the adolescents of authoritative parents (i.e., those who are warm and high in behavioral control but low in psychological control) evince positive developmental outcomes is that they (a) are more likely to see their parents as legitimate authorities and believe themselves obliged to obey them, (b) are more likely to internalize their values, and (c) are thus both more open to parental socialization and more likely to make autonomous decisions consonant with parental values. Research on the association of legitimacy beliefs and parenting has been consistent with this

prediction. Early adolescents who believe that their parents have legitimate authority to regulate personal issues, such as who their friends are or how they dress, also report that their parents have more knowledge of their lives (Smetana & Daddis, 2002). Adolescents' beliefs about their obligation to disclose information to parents, as well as greater trust, and in the case of personal issues, more parental acceptance, predicts more disclosure and less secrecy (Smetana, Metzger, Gettman, & Campione-Barr, 2006). Parents whose knowledge of their adolescents' lives stems from voluntary disclosure are most likely to have adolescents with lower levels of problem behavior (Crouter, Bumpus, Davis, & McHale, 2005; Kerr & Stattin, 2000). Further, adolescents' decisions to disclose information to parents depends upon both the adolescents' perception that parents are supportive (Crouter et al., 2005; Darling, Cumsille, Caldwell, & Dowdy, 2006) and, in case of disagreement, adolescents' beliefs that they are obliged to obey parents in spite of disagreement (Darling et al., 2006). Adolescents who express general agreement with parents and who feel obliged to obey parents across a range of issues are more likely to obey parents than are their peers, controlling for parental support and monitoring. Examining variability within adolescents across different issues and controlling for both the presence of rules and the parents' reports of rule enforcement, adolescents are most likely to obey parents in situations where they agree with parents, believe that parents have legitimate authority, and believe that they are obliged to obey parents in spite of disagreement (Darling et al., 2007).

Research on adolescents' and parents' beliefs about the legitimacy of parental authority and the obligation to obey emerged from research on social cognition and moral development (e.g., Turiel, 1983) and has primarily focused on (a) differences in legitimacy beliefs depending upon the domain of the issue in question; (b) normative, age-related differences in adolescents' and parents' legitimacy beliefs; and (c) differences in the legitimacy beliefs of adolescents and parents. Research in the United States in samples of African-, Cuban-, Chinese-, European-, Filipino-, and Mexican-American backgrounds (e.g., Darling et al., 2005; Fuligni, 1998; Smetana, 2000) and in samples from Brazil, Chile, China, Japan, and the Philippines (e.g., Darling et al., 2005; Hasebe, Nucci, & Nucci, 2004; Nucci, Camino, & Sapiro, 1996; Yau & Smetana, 2003) has yielded strikingly consistent results. Adolescents and their parents are more likely to judge issues that are defined as moral (e.g., hitting or stealing), prudential (e.g., drinking, using drugs), and conventional (e.g., talking back to parents, cursing) as legitimately within the domain of parental authority, and to judge issues defined as personal (e.g., choice of friends or extracurricular activities) as outside legitimate parental control (see Smetana, 1997, for a detailed review of this perspective). As adolescents become older, both they and their parents define more issues as falling outside the legitimate domain of parental authority, although parents lag behind adolescents in the speed of this transition (Smetana, 2000). Much of this normative contraction in the legitimate domain of parental authority occurs in the personal domain and in multidomain issues that have personal aspects.

Differences between adolescents' and parents' beliefs about the legitimacy of parental authority have been hypothesized to cause conflict within the family, especially in early and middle adolescence (Smetana, 1996). Parental assertion of control over personal issues is also associated with adolescents' perceptions that parents are exerting inappropriate psychological control (Smetana & Daddis, 2002) and with more internalizing symptoms (Hasebe et al., 2004). Nucci and Smetana have argued that adolescents' assertion of control over personal issues is a fundamental part of the development of healthy autonomy (Nucci, Killen, & Smetana, 1996; Smetana, Crean, & Campione-Barr, 2005). Moderate amounts of resistance to parental authority, or even subversion, may be a sign of healthy development (Smetana et al., 2005). However, premature assertion of personal control (or, conversely, premature rejection of parental legitimacy) over areas normatively defined as legitimately within parental control may be both symptomatic of poor parent–adolescent relationships (Darling et al., 2005) and indicative of problematic developmental pathways (Steinberg & Silverberg, 1986).

Although there is a clear, age-related decline in the range of issues that adolescents and parents believe to be within the legitimate sphere of parental authority, there is considerable within-age variability in adolescents' endorsement of parental authority (Darling et al., 2005). In a recent article in which latent class analyses were used to examine the patterning of adolescents' legitimacy beliefs (Cumsille, Darling, Flaherty, & Martínez, 2006), three distinct patterns emerged. In the first pattern (parent centered), adolescents were likely to grant parents legitimacy over both multidomain and prudential issues and were more likely than their peers to grant parents authority over personal issues. In the second pattern (adolescent centered), adolescents were unlikely to grant parents legitimacy over personal, prudential, or multidomain issues. In the third pattern (shared), adolescents clearly differentiated parental legitimacy across domains and were likely to grant parents authority over prudential issues but unlikely to grant them authority over personal issues. Analogous patterns emerged among early, middle, and late adolescents, with the parent-centered pattern most common at each age (ranging between 49% and 58% of each age group). Although cross-sectional, the proportion of adolescents evincing each pattern was relatively stable across age groups, suggesting that youth showing different patterns may be following different trajectories in the development of legitimacy beliefs.

Individual differences in adolescents' beliefs are associated with differences in adolescents' behavior in ways that may undermine or facilitate parenting. For example, adolescents who are heavy drug users tend to see substance use as a personal rather than prudential issue and thus outside the legitimate sphere of parental authority (Nucci, Guerra, & Lee, 1991). In case of disagreement, adolescents who believe that parents have legitimate authority with regard to specific issues and feel obliged to obey are (a) more likely to disclose information to parents about that issue rather than lie (Darling et al., 2006), (b) more likely to argue about the issue with parents (Cumsille, Darling, & Peña-Alampay, 2002), and (c) more likely to obey (Darling et al., 2007). Further, adolescents who believe that they are obliged to disclose to parents both disclose more to parents and are less likely to keep secrets from them (Smetana et al., 2006). We know little about where these differences in adolescents' beliefs about parental legitimacy and obligation to obey come from or how they may unfold over time. In addition, research on normative changes in adolescents' beliefs has focused on adolescents' beliefs in the legitimacy of parental authority. Much less is known about children's beliefs about their obligation to obey parents when they disagree with them. These beliefs may be particularly important in understanding decision making in situations where direct parental supervision or distal monitoring is difficult or dependent on children's willingness to disclose.

The goals of the present article were (a) to examine longitudinal change in Chilean adolescents' beliefs about the legitimacy of parental authority and their own obligation to obey parents in case of disagreement and (b) to predict individual differences in adolescents' beliefs and changes in those beliefs as a function of their own and their parents' characteristics. Adolescents were in early to middle adolescence at Wave 1 of the study (11–14 years old) and were followed once a year for 4 years. Five specific issues were addressed:

1. Do adolescents become less likely to endorse the legitimacy of parental authority and their own obligation to obey with age?
2. Is the decline in adolescents' endorsement of parental legitimacy and their own obligation to obey uniform across adolescence, or does it decline more rapidly in early adolescence than in middle or later adolescence?
3. Is the decline in endorsement of parental legitimacy and obligation to obey parallel in all domains, or does it decline more quickly in some domains than in others?
4. Are adolescents who perceive their parents to be supportive and high in monitoring more likely to endorse the legitimacy of parental authority and their own obligation to obey than those whose parents do not? Are adolescents who were relatively more involved in problem behavior less likely to endorse parental authority and their own obligation to obey?
5. Do adolescents' beliefs in the legitimacy of parental authority and their own obligation to obey decline less rapidly when they see their parents as supportive and high in monitoring? Do the beliefs of adolescents who are relatively more involved in problem behavior decline more rapidly?

Questions 1–3 provide a partial replication and extension of longitudinal research by Smetana (2000), documenting changes from ages 13 to 15 in a sample of 82 African American adolescents' beliefs about parental authority using a sample of 568 Chilean adolescents. Because adolescents ranged in age from early to middle adolescence at Wave 1 of this study, differences in belief trajectories from early to middle and from middle to late adolescence could be compared. Based on prior research, it was hypothesized that normative declines would be most rapid in the personal and multidimensional domains. Because previous research has suggested that a normative shift in parental authority occurs during the pubertal transition, it was further hypothesized that the decline in endorsement of parental authority would be more marked in the transition from early to middle adolescence than during later periods (Smetana, 1996).

Questions 4 and 5 focus on individual differences and changes in adolescents' beliefs about the legitimacy of parental authority and their own obligation to obey as a function of initial parental support and monitoring and initial adolescent problem behavior. The former question focuses on overall differences in adolescents' beliefs across ages (Which adolescents are most likely to believe that parents have legitimate authority and that they are obliged to obey?).

Although research has consistently shown that monitoring and support are associated with more positive development outcomes (Steinberg & Silk, 2002), the underlying processes linking parent attributes and adolescent outcomes have been studied less frequently, and until recently, the empirical literature has neglected the adolescent as an active participant in the processes. It was hypothesized that adolescents who see their parents as supportive and expressing interest in their adolescents' lives through monitoring will be more likely to believe that parents have legitimate authority and themselves as obliged to obey (Darling & Steinberg, 1993) and that adolescents who are relatively more involved in problem behavior will be less likely to do so (Jessor & Jessor, 1977; Kerr et al., 1999; Moffitt, 1993; Nucci et al., 1991).

Question 5 focuses on individual differences in the trajectories of adolescents' beliefs over time. It is possible that children come into adolescence with different beliefs about parental authority and that these relative differences remain stable over time. For example, adolescents who see their parents as supportive may also see them as more legitimate, but the decline in legitimacy endorsement over time may be parallel for adolescents with supportive and less supportive parents. Alternatively, seeing parents as supportive may slow the rate at which adolescents' belief in the legitimacy of parental authority declines. These two models of change have very different implications for understanding the association of parenting and adolescents' characteristics with individual differences in adolescents' legitimacy beliefs.

The Chilean Family Context

Chilean adolescents' relations with their parents have not been studied extensively. Chilean culture has been changing rapidly due to urbanization and outside-media influences from Europe, the United States, and other Latin American countries (Instituto Nacional de la Juventud, 1999). In addition, Chile is in the midst of a profound cultural shift resulting from the fall of the military dictatorship and the reinstitution of democracy in 1990. Political changes, combined with rapid economic development, have resulted in a sharp rejection of authoritarian values and liberalization of social and sexual norms (Martínez, Cumsille, & Thibaut, 2006). Reflecting these changes, contemporary Chilean parents appear to be relatively uncomfortable with direct assertion of control and rule enforcement and report that they are less authoritarian and less likely to use power-assertive parenting techniques than did their own parents (Martínez et al., 2006). For example, parents reported discussing areas of parent–adolescent disagreement but leaving the decision to adolescents 78% of the time, letting the adolescent do as they wanted 11% of the time, and enforcing rules only 11% of the time (Darling et al., 2007). Chilean youth appear to share this discomfort with parental control. Chilean youth are less likely than Filipino or U.S. youth to (a) believe that their parents have the right to govern their behavior (particularly with regard to prudential areas, such as alcohol use or curfew), (b) believe that they are obliged to obey parents when they disagree, or (c) agree with parents (Darling et al., 2005). More than 85% of Chilean youth think of themselves as different from the adult generation both in how they think and in how they act (Martínez et al., 2006). Across all social classes, younger Chileans espouse more individualistic values than older cohorts, although the society remains highly family oriented (Programa de Naciones Unidas para el Desarollo, 2002) Taken together, these findings suggest that family relations in contemporary Chile are typically close but that both parents and adolescents tend to expect less direct assertion of parental control and less strict adolescent obedience than might be typical in the contemporary United States.

Although Chile remains a socially conservative country in many ways (e.g., divorce was only legalized in the country in 2005), political and social changes in Chile have been accompanied by problems usually associated with urban youth in Western countries, including relatively high rates of alcohol use (the legal drinking age is 18), substance use, vandalism, and petty theft (Darling et al., 2007; Martínez et al., 2006). In a nationally representative sample, 83% of Chilean youth reported onset of sexual intercourse prior to age 20, 15% reporting onset prior to age 15, and 24% of 15- to 19-year-olds reported that their last sexual encounter was in a casual relationship rather than with a boyfriend, girlfriend, or fiancé (Instituto Nacional de la Juventud, 1999). Despite these changes, adolescents tend to hold fairly traditional ideas about gender roles within the family. These beliefs about the division of parental responsibilities may reflect the fact that fewer Chilean women participate in the paid labor force than in any other South American country (39%; Martínez et al., 2006).

Method

Participants and Procedure

The sample included 568 sixth to ninth graders recruited to participate in a longitudinal study of parenting, adolescent risk, and resilience (mean Wave 1 age = 12.95 years, *SD* = 0.99, range = 11–14 years), each of whom had participated in at least two waves of the 4-year study. Participants were recruited from seven schools from two counties in Santiago, Chile (92% of 14- to 17-year-old Chileans are enrolled in school; Martínez et al., 2006). Schools are typically organized from Grades 1 to 8 and from Grades 9 to 12; therefore, sixth and seventh graders experienced a transition from primary to secondary school during the study's duration. Schools were selected to represent the diversity of socioeconomic status (SES) observed in the Chilean educational system and included two private, one subsidized private, and four public schools, thus oversampling for lower SES students. Fifty-six percent of the sample were female. Seventy-four percent of the adolescents lived with both biological parents at the time of the first assessment.

Public schools were contacted through the board of education of each county. Private schools were contacted directly. Consistent with Chilean regulations and research practices, active adolescent assent and passive parental consent were used. After mailing descriptions of the study home to parents, students were given oral and written information about the study's purpose and procedure, invited to sign written consent forms, and completed questionnaires within their classrooms. Consent procedures and survey administration were carried out by upper-level psychology students trained by the researchers. Participants received a candy bar as a thank you for their participation. During each wave of the study, fewer than 2% of students declined to participate or had permission withheld by parents. Subsequent survey administrations took place approximately 1 year apart. Because of budgetary limitations, follow-up data collection for each wave was limited to only a randomly selected subset of the original sample. During follow-up, classrooms within schools and then individuals within classrooms were selected at random. In addition, because student contact and data collection were entirely school based, somewhat less than 5% of total data loss occurred due to absences or because students changed or left school during the course of the study. For these analyses, data are included for all individuals who participated in at least two waves of data collection, including both Wave 1 and Wave 2, when predictor variables (parental monitoring and support and substance use) were measured. Thirty-three percent of students provided data for 2 years of the study, 44% for 3 years, and 23% for 4 years. Years of participation did not vary by age, family type, adolescent problem behavior, or parental support or monitoring ($p > .05$).

Adolescents provided information on demographic background, attitudes toward school and civic involvement, activities, self-esteem, problem behavior, parenting practices, and risk and protective factors. In addition, adolescents each completed a Strategic Disclosure Questionnaire (Darling et al., 2007), with adolescents answering six questions about each of 20 different issues. Issues were selected to represent areas that are frequent sources of parent-adolescent disagreement and were identified through review of the extant literature and focus groups. Questionnaires were developed jointly by native American English and Chilean speakers, with the translation of individual items discussed and reviewed by bilingual, native Chilean speakers. Cultural appropriateness of stems and questions were validated in a separate pilot study involving more than 200 Chilean adolescents. Measures are described here in English.

Measures

Legitimacy of parental authority and obligation to obey. To assess adolescents' legitimacy beliefs, adolescents were asked, "Is it okay for your parents to set rules about this issue?" for each of the 20 issues on the Strategic Disclosure Questionnaire (0 = *no*, 1 = *yes*). Obligation to obey was assessed by asking adolescents "If you disagree with your parents, do you have to obey?" (0 = *no*, 1 = *yes*). Across issues and wave of data collection, adolescents reported that they believed that parents had the right to set rules for 57.7% of issues and that they were obliged to obey for 59.9% of issues. As expected, adolescents' beliefs about legitimacy and obligation to obey were related, although not identical. If an adolescent endorsed parental legitimacy for a given issue, they also endorsed their own obligation to obey 83.7% of the time. If adolescents did not endorse legitimacy for an issue, they reported that they were obliged to obey only 27.7% of the time.

Between-Person Predictors

Parental monitoring. At Wave 1, adolescents reported on the extent to which their mothers and fathers tried to know (a) who their friends were, (b) what they did after school, (c) what they did in the evenings, (d) what they did with their free time, (e) how they spent their money, and (f) how they were doing in school. Adolescents responded on a 1–3 scale, with 3 indicating *parents tried a lot* and 1 indicating *parents did not try.* A mean score was calculated (mother $\alpha = .80$, father $\alpha = .86$), and the maximum of either mother or father monitoring was used as an indicator of parental monitoring ($M = 2.47$, $SD = 0.49$). The decision to use the maximum of mother or father score rather than a mean was made because the normative difference in ratings of maternal and paternal monitoring and the amount of missing father data resulted in an artificial inflation of monitoring scores for those who reported on only one parent.

Parental support. Because parental support was not measured at Wave 1, a Wave 2 assessment was used. Using a 5-point scale, adolescents reported on the extent to which they agreed with four items describing each of their parents (sample items: "My mother/father likes to spend time just talking with me" and "I can count on my mother/father to help me with my problems"; mother $\alpha = .80$, father $\alpha = .83$). Items were recoded such that high scores indicated high support. Mean scores were calculated for each parent. The maximum of mother or father score was used as an indicator of parental support ($M = 4.36$, $SD = 0.79$) to reduce artificial bias favoring adolescents who reported on only one parent.

Problem behavior. At Wave 1, adolescents reported on how frequently they had engaged in five problem behaviors from *never in my life* (1) to *more than once in the last month* (5). Sample items included damaged public or private property, taken something from a store without paying for it, been in a fist fight, brought a weapon to school, or been in a fight that resulted in an injury in which someone needed to be seen by a doctor or nurse ($M = 1.31$, $SD = 0.59$). (Substance use was excluded because of normative age differences in use.)

Within-Person Predictors

Time. Time was coded from 0 to 3, with 0 indicating *baseline assessment* and 3 indicating *Wave 4 of the study.*

Domain. Because issues in this study were chosen to reflect common sources of parent–adolescent disagreement, rather than a specific theoretical model, issue domain membership was empirically derived from factor analysis of adolescents' ratings of parental legitimacy using a separate sample (Darling et al., 2005). Each issue was classified into one of five domains: personal (choice of friends, what you wear, use of free time, extracurricular activities, use of money), prudential (smoking, alcohol, and drug use), parent expectations (time on the telephone, homework, school performance), opposite-sex relations ("Your relationships with the opposite sex [phone calls, going to dances or out with mixed sex groups, dating]" and "Your relationship with your boyfriend or girlfriend [time you spend together, privacy you are allowed, how serious you are, your sexual relationship]"), and multidomain (type of video viewed, spending time with people parents do not like, unsupervised time with friends, where you go with friends, hanging out after school and after dinner, curfew). Empirical classification differs from prior theoretical research on domains primarily in the separation of the opposite-sex relations and personal domains. Issues classified here in the opposite-sex relations domain are quite similar to those classified as multifaceted in stimulus material currently used by Smetana (e.g., Smetana et al., 2006).

Analytic Strategy

A series of analyses was undertaken predicting (a) change in adolescents' beliefs as a function of age and time, (b) change in adolescents' beliefs as a function of age and time run separately by domain, and (c) individual differences in adolescents' beliefs as a function of age, time, parenting, and adolescent problem behavior. Analysis of these data was complicated by the nonindependence of each participant's assessment of 20 issues for up to four waves of data collection, which violates the assumptions of techniques such as multiple regression, and thus artificially inflates error terms. In this study, data were available from 568 adolescents reporting on 22,589 issues over the four waves. Hierarchical general linear modeling (HGLM) was specifically designed to adjust the degrees of freedom in the model to compensate for nonindependence of observations (Raudenbush & Bryk, 2002). In these analyses, HGLM was used to parse variance in adolescents' beliefs into a participant component (differences between different adolescents' beliefs predicted from adolescents' age and gender, parental monitoring, parental support, and adolescent problem behaviors) and a within-adolescent issues component (differences in beliefs with regard to specific issues predicted from domain membership and time). Because of its structure, all within-person HGLM analyses effectively control for between-person differences. In these analyses, therefore, analyses predicting within-person differences in legitimacy beliefs and obligation to obey from time and domain controlled for between-person differences in gender, age, and initial perceived parental support and monitoring and adolescent problem behavior. All HGLM analyses were performed using the Bernoulli procedure with logit link for dichotomous outcomes, such that predictors discriminate between two dichotomous choices. Because Level 1 variance is heterogeneous in Bernoulli logit-link analyses (Snijders & Bosker, 1999), the percentage of variance attributed to each level and explained by each model was not calculated. Unit-specific models are reported.

Results

Legitimacy of Parental Authority and Obligation to Obey as a Function of Age, Time, and Domain

A series of two-level (issue within adolescent) HGLM Bernoulli logit-link analyses were used to test the hypotheses that (a) older adolescents would be less likely to endorse the legitimacy of parental authority and (b) belief in the legitimacy of parental authority would decrease over time. In these analyses, Wave 1 age was used to predict between-adolescent differences in adolescents' beliefs about legitimacy. Time (Years 0, 1, 2, 3) was used to predict within-adolescent differences in beliefs. The interaction between Wave 1 age and time tested the hypothesis that the time-related decline in likelihood is steeper for younger adolescents than for older adolescents. Analyses were first run for all issues and then run separately by domain. A series of three-level HGLM models (issue within domain within person) were used to test for domain difference in the intercepts, age, and time model coefficients (Level 1 $df = 22589$, Level 2 $df = 2752$, Level 3 $df = 550$). In preliminary analyses, a curvilinear time function (time^2) was also added to the models, with mixed results. Based on the recommendations of Raudenbush and Bryk (2002) regarding the fitting of longitudinal models with a small number of measurement points and the significant interaction of initial age and time of measurement, the decision was made to use the more parsimonious linear model for the final analyses. Curvilinear results are very similar to those presented here and are available from the first author.

The predicted probabilities of endorsing parental legitimacy and obligation to obey for all items are graphed in Figure 1. In this figure, separate cohorts are indicated by different lines (i.e., adolescents in the study from ages 11 to 14, 12 to 15, 13 to 16, and 14 to 17). The likelihood of endorsing parental legitimacy and the obligation to obey decreased with both initial age and time ($ps \leq .000$). Adolescents who entered the study at an older age were less likely to endorse parental legitimacy or their own obligation to obey. Predicting within-person change, endorsement decreased with time. The interactions between both legitimacy and obligation to obey with Wave 1 age were significant ($ps \leq .000$), such that the within-person decrease in legitimacy over time was greater for those adolescents who had started the study at a younger age.

Results of both the two- and three-level HGLM models calculated separately by domain are reported in Table 1. The likelihood that adolescents would endorse parental authority varied by domain ($p \leq .01$), with adolescents most likely to endorse parental authority in the prudential domain and least likely to endorse parental authority in the personal domain. In all domains, adolescents who were youngest at Wave 1 were most likely to endorse parental authority ($p \leq .05$). Within adolescents, the likelihood of endorsing parental authority declined with time ($p \leq .05$). The difference in endorsement of legitimacy between older and younger adolescents was largest in the prudential domain and smallest for multidomain issues. The within-adolescent decline in legitimacy with time was also steepest in the prudential domain and shallowest for multidomain issues. In the personal domain only, the decline in endorsement of legitimacy was steeper for younger adolescents than for older adolescents ($p \leq .01$).

Identical analyses were carried out predicting between- and within-adolescent differences in the likelihood that adolescents believed that they were obliged to obey parents in case of disagreement. Results of the analyses predicting obligation to obey paralleled those predicting legitimacy of parental

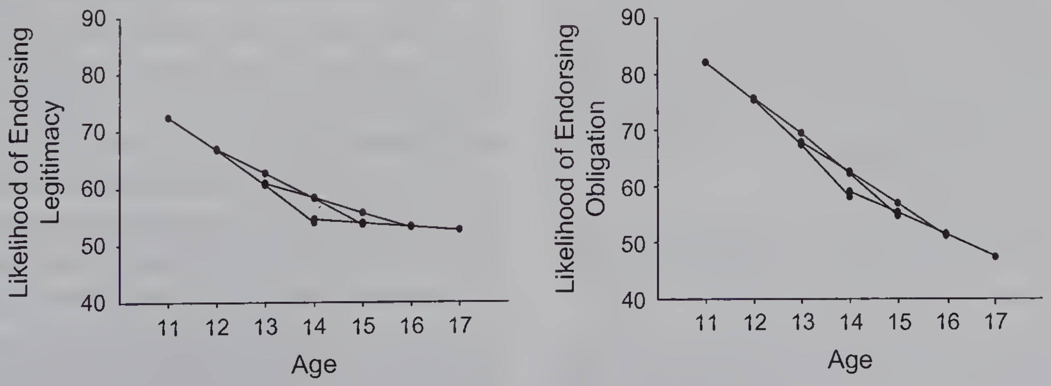

Figure 1. Predicted likelihood of endorsing parental legitimacy and obligation to obey by age.
Note. Separate lines indicate adolescents who began the study at different ages.

Table 1

Results of HGLM Analyses Predicting Adolescents' Beliefs That Issues Are Within the Legitimate Domain of Parental Authority and That They Are Obliged to Obey From Age, Time, and Domain

	Domain				
	Personal	Opposite-sex relations	Prudential	Expectations	Multidomain
			Legitimacy

Within person					
Time	-0.16^{***}_{ac}	-0.19^{***}_{ac}	-0.27^{***}_{c}	-0.11^{*}_{ab}	-0.06^{*}_{b}
Time × Wave 1 Age	0.09^{**}	0.09	0.10	0.09	0.10
			Obligation to obey		
Between person					
Intercept	0.15^{*}_{a}	0.49^{***}_{b}	1.93^{***}_{c}	1.35^{***}_{d}	0.89^{***}_{e}
Wave 1 Age	-0.51^{***}_{ac}	-0.34^{***}_{b}	-0.54^{***}_{a}	-0.19^{*}_{bc}	-0.32^{***}_{b}
Within person					
Time	-0.37^{***}_{a}	-0.26^{***}_{bd}	-0.40^{***}_{ab}	-0.17^{***}_{cd}	-0.15^{***}_{c}
Time × Wave 1 Age	0.13^{***}	0.08	0.05	−0.06	0.08^{**}
			Two-level model Approximate *df*		
Between person	559	558	557	559	559
Within person	7217	2844	2844	2887	7175

Note. Positive coefficients indicate greater likelihood of endorsing legitimacy and obligation to obey. Results of the three-level HGLM analyses comparing the coefficients of models of different domains are summarized in the subscript. Within rows, coefficients that share lowercase subscripts are not significantly different from one another ($p > .05$). HGLM = hierarchical general linear modeling.
$^{*}p \leq .05$. $^{**}p \leq .01$. $^{***}p \leq .001$.

authority (Table 1, bottom). Adolescents were most likely to endorse their own obligation to obey for issues in the prudential domain and least likely to endorse these beliefs in the personal domain ($p \leq .001$). In all domains, younger adolescents were more likely to believe that they were obliged to obey parents than were older adolescents ($p \leq .05$), although the age-related differences varied by domain. Interestingly, although adolescents were least likely to feel obliged to obey in the personal domain, this domain also showed a relatively large age-related difference in endorsement of parental legitimacy. Predicting within-adolescent change, the likelihood that adolescents believed that they were obliged to obey declined with time in all domains ($p \leq .001$). For personal and multidomain issues, endorsement of obligation to obey declined more steeply for younger adolescents than for older adolescents ($p \leq .01$).

Together, these analyses confirm previously reported differences in adolescents' beliefs about the legitimacy of parental authority and their own obligation to obey. Cross-sectional age differences were replicated by within-person declines in endorsements with time. Overall, the decline in the likelihood that adolescents would endorse the legitimacy of parental authority and their own obligation to obey was steeper for younger adolescents than for older adolescents. However, this interaction was only statistically significant in the personal domain and, for obligation to obey, for multidomain issues.

Individual Differences in Adolescents' Beliefs as a Function of Parents' and Adolescents' Characteristics

A series of two-level (issue within adolescent) HGLM Bernoulli logit-link analyses were conducted to examine the hypotheses that (a) adolescents who initially described their parents as relatively supportive and high in monitoring would be more likely to grant parents legitimacy and feel that they were obliged to obey over the course of the study and (b) adolescents who were involved in relatively high initial rates of problem behaviors would be less likely to do so. As in the previous analyses, analyses were first conducted for all items and then run separately by domain. Between-adolescent differences in adolescents' beliefs were predicted from parental support, parental monitoring, and problem behavior, controlling for initial age and gender. As in the previous analyses, within-adolescent differences were predicted by time. We also tested hypotheses that the decline in endorsement over time would be smaller for older adolescents and for adolescents whose parents were relatively supportive and high in monitoring, and steeper for adolescents who were initially more involved in problem behavior. In these analyses, variables predicting between-adolescent differences in legitimacy beliefs were centered around the grand mean. Time was entered uncentered, with 0 representing the first wave of data collection. Because previous research indicated that beliefs about parental legitimacy varied by parents' marital status and SES (i.e., Nucci, Camino, et al., 1996; Smetana, 2000; Smetana, Yau, Restrepo, & Braeges, 1991), preliminary analyses were undertaken in which parents' marital status and education were used as predictors. The variables neither predicted adolescents' beliefs nor moderated the association of age or time with beliefs in this sample, and these variables were dropped from subsequent analyses.

Results of the combined model are illustrated in Figure 2. Differences in the predicted likelihood of endorsing legitimacy and obligation are plotted for adolescents who were high in problem behavior and whose parents were low in perceived warmth and monitoring (high risk) and for a comparison group of adolescents who were low in problem behavior and whose parents were high in perceived warmth and monitoring (low risk). High and low problem behavior, warmth, and monitoring were defined by the 25th and 75th percentile. In this figure, separate cohorts are indicated by different lines. In the combined model, younger adolescents were more likely to grant parents legitimate authority than were older adolescents and, looking within adolescents, grew less likely to do so with time ($ps \leq .001$). As in the previous analyses, the decline in endorsement of parental authority was steeper for younger adolescents than for older adolescents ($ps \leq .001$). Both higher initial monitoring and support were associated with greater likelihood of endorsing parental legitimacy ($p \leq .005$) and obligation to obey ($p \leq .05$) over the course of the study. Adolescents who initially reported higher rates of problem behavior were less likely to endorse parental legitimacy or obligation to obey ($p \leq .001$). The decline in endorsement with time did not vary by initial perceived monitoring or warmth ($p > .09$). The decline in adolescents' endorsement of the legitimacy of parental authority (but not obligation to obey) was less steep for those initially high in problem behavior ($p = .005$).

Results of the two-level HGLM models calculated separately by domain are reported in Table 2. In all domains, younger adolescents were more likely to grant parents legitimate authority than were older adolescents and, looking within adolescents, grew less likely to do so with time ($p \leq .01$). For personal and multidomain issues, the decline in likelihood of endorsement with time was steeper among the younger adolescents than among the older adolescents ($p \leq .01$). A similar trend was found for opposite-sex relations issues ($p = .055$). Boys were more likely to grant parents authority over issues in the personal and expectations domains but less likely than girls to grant parents authority over issues in the opposite-sex relations domain.

Although parenting predicted legitimacy beliefs in all domains except for opposite-sex relations, there was little evidence that perceived parents' characteristics moderated the decline in adolescents' legitimacy beliefs with time. Adolescents who described their parents as relatively supportive were more likely than their peers to believe that parents had legitimate authority over personal, prudential, and multidomain issues ($p \leq .05$). Adolescents who described their parents as relatively high in monitoring were more likely to believe that parents had legitimate authority over issues in the

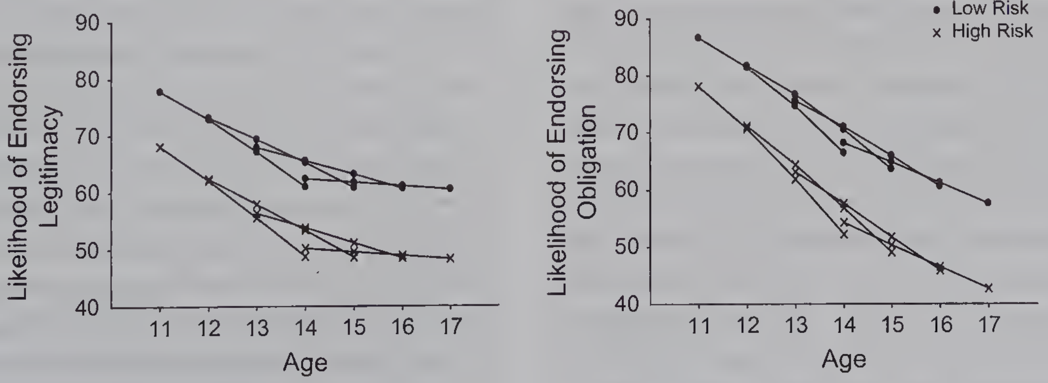

Figure 2. Predicted likelihood of endorsing parental legitimacy and obligation to obey by age. Trajectories of adolescents who are low in parental monitoring and warmth and high in problem behavior (high risk) and adolescents who are high in monitoring and warmth and low in problem behavior (low risk).

Note. Separate lines indicate adolescents who began the study at different ages.

expectations domain and over multidomain issues ($p \le .01$). Of the 10 interactions between parenting and time, only 1 was statistically significant. In the parent expectations domain only, the decline in the likelihood of endorsing parental legitimacy with time was steeper for adolescents who described their parents as high in monitoring than for their peers ($p \le .01$). As hypothesized, adolescents who were initially more involved in problem behavior were less likely to endorse parental legitimacy for personal, opposite-sex relations, prudential, and multidomain issues ($p \le .05$). For multidomain issues only, adolescents who were involved in problem behavior were less likely to endorse parental authority, but their beliefs declined less over time as well ($p \le .01$), indicating a potential floor effect.

Results of the domain-specific analyses predicting adolescents' obligation to obey are reported in the bottom of Table 2. In all domains, younger adolescents were more likely to believe that they were obliged to obey parents in case of disagreement than were their older peers ($p \le .001$). Within persons, adolescents grew less likely to feel obliged to obey with time ($p \le .001$). For both personal and multidomain issues, the decline over time in likelihood of believing one was obliged to obey was steeper for younger adolescents than for older adolescents ($p \le .001$). As hypothesized, in the opposite-sex relations, prudential, and expectations domains and for multidomain issues, adolescents who reported positive parenting were relatively more likely to feel obliged to obey than their peers. Greater likelihood of endorsing their own obligation to obey was predicted by higher parental monitoring for prudential, expectations, and multidomain issues ($p \leq .05$). Higher parental support was associated with greater likelihood of believing one was obliged to obey for opposite-sex relations and multidomain issues ($p \leq .05$). Adolescents' beliefs about personal issues were not predicted by perceived parenting. Contrary to our hypothesis, parenting did not moderate changes in adolescents' beliefs about their own obligation to obey over time. As hypothesized, adolescents who were initially more involved in problem behavior were less likely to believe that they were obliged to obey parents in case of disagreement ($p \leq .05$). Contrary to our hypothesis, when examined by domain, initial problem behavior did not moderate change in beliefs over time.

Discussion

The purpose of this article was to examine normative change and individual differences in adolescents' beliefs about the legitimacy of parental authority and obligation to obey. These findings replicate and confirm prior cross-sectional (e.g., Darling et al., 2005; Nucci, Camino et al., 1996; Smetana, 1988; Yau & Smetana, 2003) and longitudinal (Smetana, 2000) research showing that as adolescents grow older, they are less likely to believe that issues are within the legitimate domain of parental authority and that they are obliged to obey parents in case of disagreement. This consistency with prior research reinforces interpretation of the contraction of adolescents' understandings of the legitimate domain of parental authority as a reflection of the development of adolescent autonomy, effectance, and agency that is consistent across cultures (e.g., Nucci, Killen, et al., 1996; Smetana et al., 2005). It is notable that these findings have now been replicated in cultures that are strict and parent centered (e.g., China; Yau & Smetana, 2003) as well as those that are relatively low in adolescents' endorsement of parental legitimacy and obligation to obey and in which parents are reluctant to exert control (e.g., Chile; Darling et al., 2005, 2007).

Overall, the sharpest decline in adolescents' endorsement of parental legitimacy and obligation to obey occurs during early adolescence in our sample, growing less steep as adolescents move from middle into later adolescence. Early adolescence is the period during which the gap between adolescents' and their parents' beliefs about legitimacy is largest (Smetana, Yau, & Hanson, 1991). Rapid change in adolescents' beliefs during this period may be one of many factors contributing to the realignment of power relations during the pubertal transition (Collins, 1992). Although adolescents' endorsement of parental legitimacy and their own obligation to obey declines for issues in all domains, the relatively steep decline during early adolescence is seen most clearly in the personal domain for parental legitimacy and for personal and multidomain issues with regard to obligation to obey. Six of the seven multidomain issues combine elements of the personal and prudential domains (e.g., "spending time with people your parents don't like" and "spending time with friends when no adults are around"). Prior work has shown that early adolescents broaden the number of issues they consider to be within the personal domain and that this change is largely responsible for the difference between the boundaries adolescents and parents set for legitimate authority (e.g., Smetana, Daddis, & Chuang, 2003). In particular, adolescents reason about issues that are conceptually defined as multidomain as if they were personal.

In addition to the biological and cognitive changes associated with the transition from early to middle adolescence, it is important to note that social transitions are also likely to contribute to changes in beliefs during this period. In Chile, the transition from early to middle adolescence is marked by a transition from primary to secondary school. Chilean youth also begin spending considerable time socializing with friends on weekends during early adolescence, particularly during the late evening and early morning hours. Although most socializing occurs in family homes (Martínez et al., 2006), adolescent gatherings become both less family centered and less supervised at this age. Spending times in these settings may thus provide an impetus for changing adolescents' beliefs about parental legitimacy and their own obligation to obey, particularly with regard to issues that have elements that are both personal and prudential. More detailed longitudinal analyses that focus on specific contextual and behavioral changes and their temporal relationship to changing legitimacy beliefs would shed additional light on the processes underlying normative change.

The present article extends previous research by focusing on how characteristics of both parents and adolescents predict individual differences in the trajectory of normative change in adolescents' beliefs over time. Adolescents who perceived their parents to be supportive and high in monitoring at the beginning of the study were more likely to endorse parental legitimacy and their own obligation to obey both contemporaneously and in subsequent years. Specifically, adolescents who perceived their parents to be supportive were more likely to believe that parents had legitimate authority over personal, prudential, and multidomain issues. They were more likely to feel obliged to obey with regard to issues in the opposite-sex relations and multidomain domains. Adolescents who perceived their parents to be high in monitoring were more likely to endorse legitimacy and obligation to obey for issues in the parental expectations and multidomain domains and more likely to feel obliged to obey in the prudential domain as well.

The finding that good parenting predicts adolescents' beliefs about parental legitimacy highlights the interrelationship of parent and adolescent attributes that have been prominent in recent developmental research (Crouter & Head, 2002). Support and monitoring are two components of the constellation of parent attributes associated with the authoritative parenting style. The present findings and those linking adolescents' beliefs with adolescents' disclosure and obedience (Darling et al., 2007) are consistent with the hypothesis that adolescents' legitimacy beliefs are a central link between authoritative parenting and positive adolescent outcomes (Darling & Steinberg, 1993). Further, authoritative parents differ from their authoritarian and permissive peers in making clearer distinctions between personal issues and other domains when regulating adolescent behavior (Smetana, 1995). Parents who are authoritarian (high in behavioral control and intrusive psychological control but relatively low in support) are more likely to set rules in the personal domain, tending to reason about them in either moral or conventional terms. Recent research suggests that adolescents whose parents attempt to regulate issues adolescents define as personal report more internalizing symptoms (Hasebe et al., 2004) and see their parents as more psychologically controlling (Smetana & Daddis, 2002). Thus, adolescents who perceive their parents to be supportive and high in monitoring are more likely to believe parents to be legitimate authorities and to believe that they are obliged to obey them. Adolescents' beliefs predict self-reported adolescent obedience (Darling et al., 2007), voluntary disclosure of information, and perceived parental knowledge (Darling et al., 2006; Smetana et al., 2006). The latter two processes are associated with positive outcomes during adolescence (Crouter & Head, 2002). In addition, because adolescents who perceive their parents to be supportive or high in monitoring are also more likely to believe that parents are legitimate authorities, they are less likely to perceive parents as intruding into their personal jurisdiction.

Adolescent attributes are also important predictors of beliefs. Adolescents who were initially more involved in problem behavior were less likely to believe that parents had legitimate authority over issues in all domains and were less likely to believe that they were obliged to obey parents when they disagreed. These individual differences in problem behavior at the beginning of the study predicted differences in the endorsement of parental legitimacy and obligation to obey both contemporaneously and at each subsequent wave of data collection. Previous research had revealed a relatively small number of adolescents (16% during early and middle adolescence, 9% during late adolescence) who were unlikely to endorse parental authority over issues in the personal, prudential, or multidomain domains (Cumsille et al., 2006). The present findings suggest that relatively high involvement in problem behavior may be one correlate of rejection of parental authority—both as legitimate and as requiring obedience. This co-occurrence of involvement in problem behavior and rejection of authority is consistent with much of what is known of the etiology of chronic adolescent delinquency (e.g., Jessor & Jessor, 1977; Moffitt, 1993; Patterson et al., 1989) and research on adolescent substance users' belief that substance use is a matter of personal discretion (Nucci et al., 1991). It should be noted, however, that prior research on adolescents' attitudes toward authority and delinquency has focused on rebelliousness or rejection of authority as a global or personality characteristic. When examined at the issue level, however, there is evidence that the voluntary disclosure of adolescents who are involved in disapproved activities is more sensitive to their own beliefs about their obligation to obey and to parental rules than is that of their peers (Darling et al., 2007). Thus, although adolescents who are relatively more involved in problem behavior are less likely to endorse parental authority or obligation to obey, they may nonetheless believe that parents are legitimate authorities in some areas and these beliefs have consequences. The direction of the causal relationship between involvement in problem behavior and adolescents' beliefs remains unclear.

This research is also unique in examining longitudinal changes in both legitimacy beliefs and beliefs in adolescents' obligation to obey. Research on normative change in adolescents' and parents' beliefs has primarily focused on beliefs about the legitimacy of parental authority. This is a natural extension of the theoretical underpinnings of social-cognitive domain theory and the processes leading to developmental change in parent–adolescent conflict (e.g., Smetana, 1999). More recently, however, researchers have begun to focus on individual differences in adolescents' beliefs and the consequences of individual differences for adolescent disclosure (Darling et al., 2006; Smetana et al., 2006) and obedience (Darling et al., 2007). Although legitimacy beliefs and beliefs in the obligation to obey are interrelated, they are not identical either conceptually or empirically. For example, U.S. adolescents who were interviewed about their reasoning about disobedience often described areas that parents can (or even should) try to control but which they do not feel obliged to obey (data available upon request). Romantic relations, where they go with friends, substance use, and other issues that combine facets of the prudential and the personal are often cited as examples of issues where adolescents acknowledge their parents' concerns but believe that their own judgment supersedes their obligation to obey. As researchers begin to try to understand the active role that adolescents play in their own development, in shaping parent – adolescent relationships, and in the socialization process, adolescents' beliefs and reasoning about their obligation to obey parents may emerge as a key concept.

Although adolescents whose perceptions of parents and problem behavior differ at the start of the study also differ in beliefs about legitimacy and obligation to obey, the developmental trajectories of their beliefs do not appear to. There is very limited evidence that change in beliefs over time varies with either initial perceptions of parenting or problem behavior. This suggests a model of normative change in adolescents' beliefs such that children enter adolescence differing in their likelihood of endorsing parental authority and obligation to obey and become decreasingly likely to do so as they move toward adulthood. In other words, all adolescents grow less likely to endorse parental authority as they get older, but some adolescents begin that decline believing that parents have the right to set rules about many areas of their lives, and others enter adolescence believing that their parents have a right to set rules about few. For example, the predicted likelihood of endorsing legitimacy by a 12-year-old adolescent who experiences low support and monitoring and is involved in problem behavior is roughly equivalent to the predicted likelihood of a 17-year-old adolescent uninvolved in problem behavior who experiences high support and monitoring. Investigation of the consequences of the premature assertion of personal jurisdiction over areas normatively defined as legitimately within parental control may offer a promising avenue for distinguishing between pseudo- and mature autonomy.

Should this work be replicated and extended, lack of variation in the decline in adolescents' beliefs in the legitimacy of parental authority and obligation to obey would be important in what it tells us about the developmental course of individual differences in adolescents' beliefs. In particular, a limited body of cross-sectional research has documented the association of family climate with individual differences in legitimacy beliefs during adolescence (e.g., Smetana et al., 2006). Cross-sectional research does not, however, allow insight into whether these differences reflect differences that existed in childhood and remained stable throughout adolescence, differences from childhood that grew larger or smaller over time, or differences that emerged only during adolescence. The present research suggests that differences in adolescents' beliefs about legitimacy and obligation to obey have already emerged prior to adolescence and remain stable, despite a normative decline. If so, the focus of future research into the sources of these differences should be on middle childhood and early adolescence rather than on the middle or the late adolescent periods.

The setting for this study, Chile, is somewhat atypical for a study of normative change and individual differences in adolescents' beliefs about parental legitimacy and their own obligation to obey. Because contemporary Chile is in the midst of a societal change perhaps analogous to that of the 1960s in the United States and Western Europe, the extent to which these findings will generalize to other social contexts or historical periods is unclear. For this reason, the consistency of these findings and previous research on normative changes in adolescents' legitimacy beliefs is reassuring. It should be noted that these findings differ from those previously reported in two ways, however. First, prior interview research conducted in Brazil (Nucci, Camino, et al., 1996) revealed social class differences in adolescents' reasoning about parental legitimacy that were not found in this Chilean sample. Although it is possible that this reflects a difference between Chilean and Brazilian society, it is perhaps more likely that these findings reflect methodological differences in how the focal constructs of the studies were assessed. In addition, the antiauthoritarian social climate of contemporary Chile may flatten social differences in adolescents' beliefs, making them more difficult to detect using survey methodology. This study also failed to replicate previously reported differences in adolescents' legitimacy beliefs as a function of family structure (e.g., Smetana, Yau, Restrepo, et al., 1991). It is important to note in this regard that recent changes in the divorce laws make marital status somewhat difficult to assess in Chile. Until 2005, legal divorce could only be obtained through the Catholic Church. It was thus very common for couples to separate and establish long-term relationships and households with new partners while remaining legally married to their first spouse. These cultural practices may muddy the distinction between marital statuses both in terms of measurement and in the way that adolescents think about marital status, thus contributing to our null findings.

The present study is limited in several respects, most importantly in that it relies solely on adolescents' self-reports, limiting causal inference. Although self-report may be the most accurate way to measure adolescents' beliefs and perceptions of parents, objective measures of parent behavior and adolescents' involvement in problem behavior would allow us to make clearer inferences. The scarcity of significant interactions between time and either perceived parenting or problem behavior, however, suggests that bias associated with concurrent reports of predictors and outcomes are minimized in these data. In addition, because HGLM controls for between-adolescent differences when modeling within-adolescent differences, reporter biases are also minimized at this level. These data are also limited by the dichotomous measurement of adolescents' beliefs about the legitimacy of parental authority and obligation to obey. Although this was a necessary compromise to facilitate gathering data in a large and varied sample, it might not fully reflect the complex beliefs that adolescents are likely to hold about parental authority. The consistency of these results with prior findings using in-depth interviews (e.g., Smetana, 1988) and surveys that allowed for multicategorical responses (e.g., Smetana & Chuang, 2001) are thus particularly reassuring. Finally, as is true of most longitudinal studies, self-selection bias is likely to have made this sample better functioning than the population of adolescents as a whole. However, this bias will tend to reduce variability in the measures, thus making our tests more conservative than they would be in a more representative sample.

Adolescence is a liminal period when youth are in the process of establishing autonomous self-regulation at the same time that many parents are still actively trying to regulate their behavior. During this period, parents may continue to monitor their adolescents and set rules for them, but the extent to which those efforts are successful depends upon the adolescents themselves. It is unlikely, for example, for adolescents to be offered drinks when their parents are standing next to them. Although adolescents' beliefs that parents can legitimately regulate their behavior and that they are obliged to obey parents' rules decline as they move toward adulthood, the starting point of that downward trajectory may partly depend upon their perception of parents and the success of socialization during childhood and early adolescence. The extent to which adolescents' beliefs about parental legitimacy and obligation to obey can be reestablished, once lost, is unclear. Individual differences in adolescents' beliefs about parental legitimacy and obligation to obey highlight the difference between rejection of parental oversight and the development of mature autonomy (Darling et al., 2005). Recent work on the central role adolescents play in the ability of parents to monitor effectively (Crouter & Head, 2002) has focused attention on the systemic nature of what have been called "parenting" processes and the active role that adolescents play in them. These results suggest that adolescents' beliefs may be an important part of that system.

The Breadth of Peer Relationships Among Preschoolers: An Application of the Q-Connectivity Method to Externalizing Behavior

Laura D. Hanish, Carol Lynn Martin, Richard A. Fabes, and Hélène Barcelo
Arizona State University

Preschoolers' ($M_{\text{age}} = 48.7$ months) social breadth (the number of peer children interact with and the frequency of these interactions) and the relations between breadth and externalizing behaviors were examined using the Q-connectivity method. After considering age, sex, and classroom effects on social breadth, children's externalizing behaviors were studied in relation to levels of social breadth across variations in frequency of exposure to peers and to patterns of decline in social breadth. Externalizing preschoolers occasionally interacted with most of their classmates. However, their individual peer networks moderately to rapidly became selective, and they engaged in repeated interactions with a relatively small number of peers. Although there were no sex effects, significant age and classroom effects were obtained.

One of the most interesting, but least studied, aspects of children's peer relationships is the substantial variation in the breadth of children's peer affiliations. Some children interact broadly with many peers, whereas others are more selective. To complicate matters, relationship patterns change over time: Friendships form, persist for short or long periods, and often dissolve, and peers move into or out of social networks. Consequently, there is both stability and fluidity, as well as marked individual differences, in children's peer affiliations (Cairns, Leung, Buchanan, & Cairns, 1995; Estell, Cairns, Farmer, & Cairns, 2002; Martin, Fabes, Hanish, & Hollenstein, 2005). It is this variability in children's social breadth (i.e., the number of peers that each child interacts with and the frequency with which each child interacts with every peer) that we highlight in the present study. To do so, we introduce the *Q-connectivity method* (Barcelo & Laubenbacher, 2005) to calculate preschoolers' social breadth. The Q-connectivity method is a variation on social network methods that involves computing the frequency with which each child interacts with every other peer and using this information to build each child's social network at increasing levels of exposure to peers.

We expected to find individual differences in children's social breadth and we hypothesized that variations in social breadth would be related to children's externalizing behavior. We focused specifically on children's externalizing characteristics because, as research on the heterogeneity of aggressive children has highlighted (Rodkin, Farmer, Pearl, & Van Acker, 2000), the fact that some aggressive children maintain successful peer relationships, whereas others have more difficulty speaks to the need to better understand the peer contexts of these children. This issue is directly relevant to the need to better understand peer contagion processes. The conditions that are necessary for peer contagion to occur remain to be documented; for example, it is not well understood whether externalizing behaviors can be spread with just a few contacts with an aggressive child or whether extended interactions are required. Examining the social breadth of externalizing children is important to this area of study because it represents their potential range of influence.

Developmental–Contextual Framework for Conceptualizing the Relations Between Social Breadth and Externalizing Behaviors in Early Childhood

Social breadth refers to the range of peer affiliates—that is, the number of peers that each child interacts with—and the frequency with which each child interacts with every peer. As such, social

breadth represents a construct that is distinct from friendship, social status, or membership in social networks because it reflects the entire social landscape of children's peer affiliations and is not limited to a particular type or quality of social interaction, although it may relate to these factors. The roots of this construct can be seen in the early work of Challman (1932) and Waldrop and Halverson (1975).

We speculate that social breadth is an organizing feature of peer relationships across the developmental life course. We also speculate that the meaning of social breadth will vary according to developmental level. For example, early in life, social breadth may reflect increasing maturity in social development. Evidence for this supposition comes from research that has shown that, across early childhood, children evidence increasingly greater preference for and competence in engaging their peers (Rubin, Bukowski, & Parker, 1998). Moreover, preschoolers' social networks become larger, denser, and more organized with age (Strayer & Santos, 1996; Vespo, Kerns, & O'Connor, 1996). Additionally, during this time, parents and teachers expect increasing sociability, and children respond to these expectations and pressures by seeking out peer interactions. However, there is still considerable variability and change in these social tendencies during early childhood, making it an ideal time to study the correlates associated with the evolution of social breadth.

The early childhood period is a particularly important developmental period to consider sex differences in social breadth. Research has suggested that, beginning around kindergarten age, boys maintain larger groups than girls. However, among preschoolers, there are fewer clear sex differences in group size, and both boys and girls tend to interact with peers in small groups (Ruble, Martin, & Berenbaum, 2006). These findings, however, pertain to the size of friendship networks and may or may not translate to social breadth. Thus, it is necessary to describe the extent to which there are sex differences in social breadth in early childhood.

It is important to note that social breadth is a construct that does not reside entirely within the child. Rather, children's social breadth reflects their own characteristics as well as those of their peers. Thus, the degree to which children exhibit greater or lesser social breadth may be as much dependent upon the mix of available peers and the match between their own characteristics and behavioral styles and those of their peers as it is an indicator of their underlying propensity to engage with others. This means that children's tendencies to engage with peers may vary from classroom to classroom, depending upon the classroom peer culture; consequently, we would expect to find classroom-related variations in social breadth as well as individual differences in social breadth that are related in meaningful ways to children's characteristics.

Looking beyond contextual and demographic characteristics, we presume that children's externalizing behaviors also contribute to social breadth. Externalizing behaviors are particularly salient in young children's social lives, and it is not surprising that the peer relationships of aggressive children tend to be sparser and less stable over time. For instance, van den Oord, Rispens, Goudena, and Vermande (2000), who collected sociometric nomination data with over 1,000 preschool children, found that children rated by teachers as having more problem behaviors (e.g., aggression, attention problems, and fear) were less likely to be members of cliques and had peer relationships that were less transitive (i.e., children were disliked by their friends' friends). Similarly, Snyder, Horsch, and Childs (1997) found that aggressive preschoolers, compared to nonaggressive preschoolers, developed fewer relationships with peers that were stable over time. Additionally, studies have demonstrated that aggressive children have lower social preference scores and are more likely to be rejected by peers than their nonaggressive counterparts (Snyder et al., 1997; Olson, 1992). Thus, we expected social breadth to be negatively related to externalizing behaviors, including physical aggression, attention problems, and anger, among young children.

The Use of the Q-Connectivity Method to Measure Social Breadth

To measure social breadth, we used a recently developed variation on social network methods called the *Q*-connectivity method (Barcelo & Laubenbacher, 2005). This is a mathematical method of modeling complex systems and their dynamics, and it is derived from the *Q*-connectivity theory for simplicial complexes and graphs (in which the graphs are diagrams with vertices and edges). The method has previously been applied in nonsocial areas, such as search-and-rescue operations (Barcelo & Laubenbacher, 2005). From a social developmental perspective, the *Q*-connectivity method makes it possible to measure aspects of peer relationships that have been difficult to study using existing methods because it allows for an assessment of the changing structure of individual children's interaction patterns with all available peers. This is made possible by *Q*, which represents exposure; thus, as *Q* increases, exposure to peers may also increase.

The *Q*-connectivity method is marked by two unique features that make this a significant innovation for the study of peer relationships. First, the *Q*-connectivity method maps networks individually for each child in the sample rather than for a group of children—for example, classmates—as a whole as is often done with traditional social network procedures (Cairns, Cairns, Neckerman, Gest, & Gariepy, 1988; Richards & Rice, 1981). This is a useful distinction to make because when networks are mapped for a group as a whole, information about networks of those children who are isolated or peripheral is sacrificed in exchange for a parsimonious representation of the social structure of the group as a whole. Thus, by using the *Q*-connectivity method, each child's unique patterns of interaction with *all* available peers are assessed.

Second, the *Q*-connectivity method capitalizes on the dynamic nature of peer interactions by repeatedly assessing the structure of children's peer interactions at differing levels of *Q*, thus providing an estimate of children' exposure to every peer. In the present study, we relied on repeated observations of children's peer interaction partners obtained over the course of a semester. This is an important feature of the *Q*-connectivity method because it provides a means for measuring the fluctuations that occur in children's peer interaction partners across a period of time. In comparison, traditional social network methods most often rely on data obtained using self-reports or sociometric nominations collected at one discrete time; thus, the resulting social networks represent aggregated views of relationships that provide relatively static pictures of children's affiliation patterns (for recent exceptions to this, see Moody, McFarland, & Bender-deMoll, 2005; Snijders, 2005).

By applying the *Q*-connectivity method to the study of social breadth, we are able to calculate multiple measures of social breadth for each child that change as a function of exposure to peers (see the Method section for details about how this is operationalized). On average, children should have a few interactions (low exposure) with many peers but more frequent interactions (high exposure) with fewer peers. By measuring social breadth at lower and higher levels of exposure, we are able to (a) examine variations in the structure and meaning of social breadth and (b) assess the drop-off of social breadth as we move across a continuum of how often children were seen playing together.

The Present Study

We described preschoolers' social breadth along a dimension representing the relative exposure to peers and examined this in relation to three aspects of externalizing behavior—namely, physical aggression, attention problems, and anger. We tested two sets of hypotheses regarding the relations between externalizing behaviors and social breadth. Both sets of hypotheses take into consideration the drop-off of social breadth as the criterion for peer exposure is increased. However, this drop-off was conceptualized differently for both hypotheses. This allowed us to explore the relations between externalizing behaviors and (a) variations in *social breadth scores* along a dimension of increased peer exposure (Hypothesis 1) and (b) variations in the *patterns of decline* (trajectories) of social breadth scores as peer exposure increased (Hypothesis 2).

Hypothesis 1. We examined the relations between externalizing behavior and social breadth at each of several consecutive levels of peer exposure. In general, we expected to find a negative relation between externalizing behaviors (physical aggression, attention problems, and anger) and social breadth, which would indicate that externalizing children interact with a smaller set of peers than do nonexternalizing children. This hypothesis is supported by previous studies that have shown negative relations between externalizing behavior and other indicators of the quality of young children's peer relationships (Snyder et al., 1997; van den Oord et al., 2000). However, we also expected that the relations would be weak and nonsignificant at low exposure because these reflect relatively short-lived peer relationships (i.e., children are only required to interact a small number of times to be counted) but significantly negative at medium to high levels of exposure because these reflect more enduring peer relationships (i.e., children are required to interact more frequently to be counted). Such a finding would support the idea that externalizing children have relationships with peers that are less stable than those of nonexternalizing children (Snyder et al., 1997).

Hypothesis 2. We also considered the possibility that there are systematic variations in the patterns of drop-off of social breadth—that children can be distinguished according to their trajectories of social breadth as peer exposure increases. For instance, some children may have a relatively high intercept, followed by a slowly declining slope, whereas others may have a relatively high intercept followed by a steeply declining slope. Still others may have a relatively low intercept with trajectories that similarly vary in steepness. We expected that these variations in patterns could be meaningfully explained by children's externalizing behaviors. An implicit assumption underlying this idea is that a person-oriented approach can be useful in identifying and categorizing variations in patterns among children (Magnusson, 1998). This type of approach has been successfully used in prior research on children's peer relationships to describe and explain the heterogeneity in children's social relationships (Rodkin et al., 2000).

We hypothesized that children could be clustered according to systematic variations in their trajectories of social breadth and that these clusters would be meaningfully differentiated by both intercepts and slopes. In particular, we expected to find one group evidencing a moderate to high intercept (which would indicate moderate to high social breadth at low peer exposure) with a steeply declining slope as exposure increases (which would indicate low stability of peer relationships). We further expected that this pattern of social breadth would characterize the children who exhibit relatively high rates of externalizing behaviors. This hypothesis is consistent with prior research that has demonstrated that the quality and duration of externalizing children's peer relationships tend to be lower than those of more competent children (Snyder et al., 1997).

Additional research questions. We also considered the relations between age and sex and social breadth, and we controlled for their effects when relevant. We expected to find significant age differences in social breadth (Strayer & Santos, 1996; Vespo et al., 1996). But previous research on sex differences in young children's peer group size has been equivocal (Ruble et al., 2006); therefore, this was tested as an exploratory hypothesis. Although prior research has been ambiguous about the likelihood of sex differences in social breadth, there is empirical support for the hypothesis that sex moderates the relation between externalizing behaviors and peer socialization processes in young children (Hanish, Martin, Fabes, Leonard, & Herzog, 2005; Zimmer-Gembeck, Geiger, & Crick, 2005). Thus, we tested for moderation by sex. Doing so is important to current efforts to understand how differences in girls' and boys' physical aggression translate to the peer culture. Finally, we also considered classroom influences. With six classrooms in this sample, we did not have a classroom sample size that was sufficiently large to fully explore the contribution of classrooms using a multilevel design. However, we were able to address this issue by testing for the amount of variance explained by classroom level variables and by controlling for classroom as a random effect.

Method

Participants

Participants were students and teachers from six classrooms in three preschools in an urban area in the Southwest. All the schools provided full-day child care. Class sizes ranged from 17 to 20. All members of each class were recruited for participation in the study; the parental permission rate was 98%. Participants were recruited across two waves over two consecutive years. Twenty-seven children participated in both waves of data collection; these children participated as target children only during their 1st year, but they were counted as peers whenever they were observed to interact with a target child during the 2nd year. The sample consisted of 97 children with complete data (complete data were not available for 8 children), with age ranging from 37 to 64 months ($M = 48.7$, $SD = 6.1$). There were similar numbers of boys (52%) and girls. Children were predominantly non-Hispanic White (55%) and Hispanic White (32%, predominantly Mexican American), with the remainder Asian American (6%), Native American (3%), and African American (3%). Family income ranged from under $10,000 to over $140,000 (median $50,000–$60,000). Almost two thirds of the children lived in two-parent families (64%).

Procedures and Measures

For the present study, parents reported on child and family demographic variables and teachers reported on children's externalizing behaviors in the classroom. Behavioral observations of children's peer interactions in the classroom were used as the basis for calculating social breadth scores.

Observations of peer interactions. During the fall semester, trained independent observers used a scan observation procedure to record children's peer interaction partners (Hanish, Martin, et al., 2005; Martin & Fabes, 2001). Observers were in children's classrooms daily ($n = 56$ days in Wave 1 and $n = 69$ days in Wave 2) during the hours in which most children were awake and in attendance (e.g., between 9 a.m. and 4 p.m., excluding nap time), and they observed children during structured (e.g., teacher-led story time) as well as during unstructured (e.g., free play) activities in the classroom and on the playground. Observers rotated through a randomly ordered list of children, observing each child for 10 s. Once observers reached the bottom of the list, they waited for approximately 5 min and then began again. Observers completed the entire list during each observation session. Midway through the semester, the list was reversed to control for any possible bias due to order of being observed.

Observations were recorded using handheld computers. A total of 28,726 usable observations were collected. An average of 252 observations per child were obtained (range = 53–484). There were no univariate outliers for the number of observations. Observers recorded whether each child was present and available for coding, present but unavailable (e.g., in the bathroom and in the director's office), or absent. Several codes were recorded for each child, but for the purposes of the present study, only the peer partner codes were relevant. Peers were coded whenever the target child's predominant activity during the 10-s scan involved direct interaction with one or more classmates (e.g., social conversation, rule-based play, interactive play, rough-and-tumble play, and aggression) or parallel play with one or more classmates (i.e., playing alongside one another in the same activity). In preschoolers, parallel play often precipitates, or occurs as a lull in the midst of, bouts of direct peer interaction. Observers recorded as many as five peer partners during each observation. A total of 24.7% of the observations included a single partner, 9.1% included two partners, 3.4% included three partners, 1.2% included four partners, and only 0.8% included five or more partners (observations of more than five peers were very rare; in these instances, the five peers who were most closely involved with the target child were coded); the rest (60.8%) had no peer play partners (i.e., solitary activities or interactions with the teacher).

Prior to beginning data collection, observers were extensively trained on the coding procedures. Reliability was assessed on a regular basis throughout the semester by having two independent observers simultaneously code the same child (obtained on 12.9% of all observations). Reliability estimates for the peer partner codes were high; percent agreement was 91% for number of peer partners and 96% for identity of peer partners. To calculate kappas, we first used a weighting technique to balance nonsquare contingency tables (due to the fact that observers could use different numbers of categories—i.e., peer IDs—in making their ratings; Stein, Devore, & Wojcik, 2005). Kappas were then calculated for data collected in Waves 1 and 2 separately, κs = .91 (95% confidence interval [CI] = 0.88 – 0.93) and .91 (95% CI = 0.89 – 0.93), respectively. These observational procedures have been used in previous studies and have demonstrated very good reliability and validity (Fabes, Shepard, Guthrie, & Martin, 1997; Hanish, Martin, et al., 2005; Martin & Fabes, 2001).

Calculation of social breadth. Social breadth was operationally defined to include all observed peer contacts, and it can be visualized graphically as well as calculated mathematically. We first describe the graphical method for representing social breadth, followed by the way in which we computed the measure. Compared to the graphs that are produced using traditional social network methods (e.g., Cairns et al., 1988; Richards & Rice, 1981), the graphs that are produced using the *Q*-connectivity method are unique along two dimensions. First, rather than producing a single graph for a class as a whole (or other specified group), separate sets of graphs are produced for each individual in the sample. Thus, we obtained 97 sets of graphs, with each set representing an individual child's set of social networks across *Q* (level of exposure). Second, rather than producing just one single graph for each individual, *Q* graphs are produced for each child, where *Q* can vary from 1 to 69 (where 69 = the maximum number of days during the semester in which observations were conducted, i.e., maximum possible exposure).

To facilitate the description of the graphs, we provide an example. In Figure 1, the set of graphs for a target child (identified as Boy 1) is illustrated. Note that the target child is not visually represented in the graphs—only his peers can be seen—instead, the target child is assumed to be above the graph and edges from the target child to the peers are assumed to be present. This decision to exclude the target child from the visual representation of the graph reduces the clutter in the graphs and improves their readability. The vertices represented in the first graph of Figure 1 correspond to the peers who were observed to interact with Boy 1 *on at least 1 day* during the semester (square vertices indicate male peers and circular vertices indicate female peers; the placement and size of the vertices on the graphs are arbitrary). The children identified as 711, 739, and 1023 were among these peers (also see Figure 2, in which the first graph for Boy 1 is enlarged for readability). Counting the number of vertices in this graph reveals that Boy 1 interacted with 13 peers at least once during the semester. There is an edge between two vertices (i.e., between two peers) if the two peers and Boy 1 interacted as a group on at least 1 day. Again, looking at the first graph in Figure 1 (and Figure 2), we see that this was the case, for example, for Peers 739 and 1023 but not so for Peers 711 and 1051. The subsequent graphs are constructed in a similar manner. For example, the vertices in the third graph represent the peers who Boy 1 was observed to interact with *on at least 3 days* during the semester (the third graph for Boy 1 is enlarged in Figure 3). For Boy 1, there were only four such peers: 711, 729, 739, and 1023. In the same manner, there is an edge between two vertices in the third graph if Boy 1 interacted with two peers as a group on at least 3 days during the semester. In Figure 1, graph $Q = 3$, we see that this was the case for 739 and 1023 but not so for 711 and 729 nor for 711 and 1023 (also shown in Figure 3). This means that although Boy 1 interacted with all these peers on at

Figure 1. Graphs illustrating social breadth for Boy 1 at $Q = 1$ through $Q = 11$.
Note. This target child was observed with no peers at $Q = 12$ or beyond. Q is operationalized as days (e.g., the value of the function at $Q = 8$ indicates the number of peers observed interacting with a target child on at least 8 days during the semester). Male peers are identified with square vertices and female peers are identified with circular vertices. The edges connecting vertices represent connections among peers and are not considered in the present study.

least 3 days, only Peers 739 and 1023 played at the same time with Boy 1 on at least 3 days. Note that, for Boy 1, after $Q = 11$, no more graphs are shown (see Figure 1). This is because Boy 1 did not interact with any children for more than 11 days during the semester. However, because there were as many as 69 days of observation, all graphs at $Q = 12$ and beyond are empty for Boy 1 and thus not depicted.

The graphs were generated using a data processing program developed for the purpose of facilitating Q-connectivity analyses. The program also outputs several measures that can be calculated from the graphs at each value of Q. The observations of each target child and his or her play partners served as input data. It is important to note, however, that observational data are not required for the use of this method. Any method of data collection that provides repeated assessments of an individual's interaction or relationship partners could be used. Examples of such methods include diary methods, beeper methods, daily self-reports, and phone

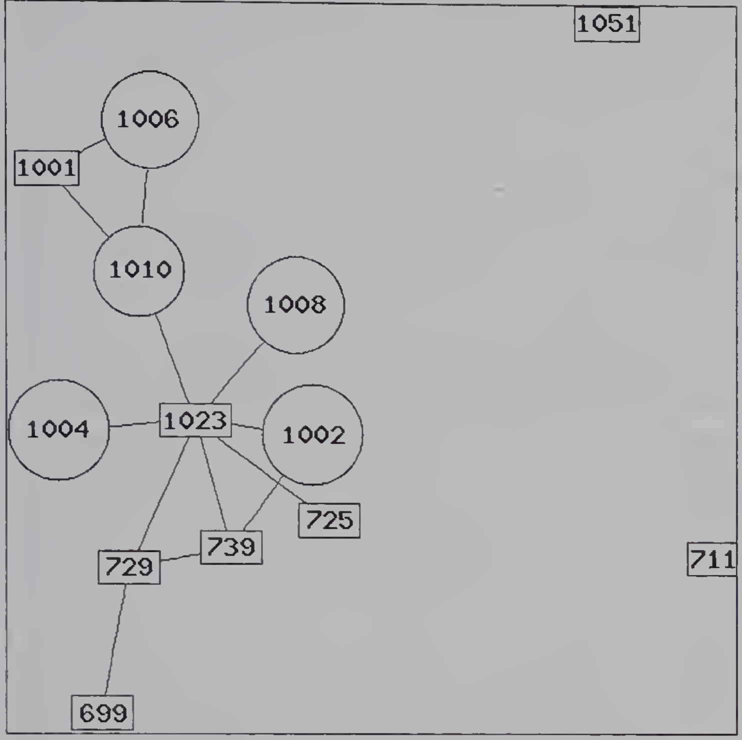

Figure 2. Enlarged $Q = 1$ graph for Boy 1.
Note. Q is operationalized as days (e.g., the value of the function at $Q = 1$ indicates the number of peers observed interacting with a target child on at least 1 day during the semester). Male peers are identified with square vertices and female peers are identified with circular vertices. The edges connecting vertices represent connections among peers and are not considered in the present study. The full set of graphs for this target child is illustrated in Figure 1.

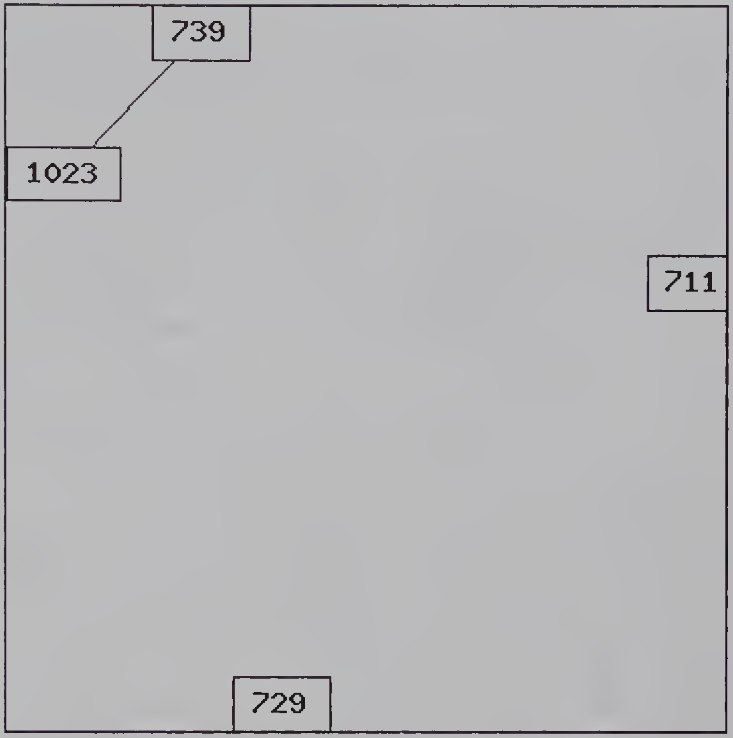

Figure 3. Enlarged $Q = 3$ graph for Boy 1.
Note. Q is operationalized as days (e.g., the value of the function at $Q = 3$ indicates the number of peers observed interacting with a target child on at least 3 days during the semester). Male peers are identified with square vertices and female peers are identified with circular vertices. The edges connecting vertices represent connections among peers and are not considered in the present study. The full set of graphs for this target child is illustrated in Figure 1.

call methods (Asakawa & Csikszentmihalyi, 2000; Birnbaum, Reis, Mikulincer, Gillath, & Orpaz, 2006; McHale, Crouter, & Bartko, 1992). Moreover, recent technological advances, including Bluetooth technology and handheld computers may facilitate multiple assessments of children's peer networks (Eagle & Pentland, 2006; Le, Hat, & Beal, 2006).

There are two important features of the data-processing program. The first is that the program systematically cleans the data by screening out data entry errors and invalid observations. The second is that the program calculates the values needed to quantify and graphically depict children's peer networks. The essential and defining feature of the Q-connectivity method entails conducting simple counts of the number of times that each target child is observed to interact with every possible peer. In the present study, we used the following method to count peers. Because we were specifically interested in using these counts to define social breadth, multiple interactions with the same peer on the same day were counted only once and only one observation with a peer per day was required for the peer to be counted on that given day. It is important to note, however, that the Q-connectivity method is flexible, such that more stringent criteria could be used to identify peers (i.e., increasing the proportion of observations per day that are required before a particular peer is "counted"). Doing so enables one to use this method to assess increasingly closer and more enduring peer relationships, in addition to social breadth. It is also possible to calculate many additional Q-connectivity parameters, which build on the counts of peers just described. For instance, one may count the edges that connect vertices in the graphs. These signify group interactions, and they are described in Hanish et al. (2007). These, and other Q-connectivity parameters, are not described in detail here because of space limitations.

To illustrate our calculations of social breadth, Boy 1, whose graphs are shown in Figure 1, was observed with exactly 13 peers at least once during the semester. His social breadth score was 13 at $Q = 1$. That child was observed with exactly four of those peers at least three times, so he had a score of 4 at $Q = 3$. Finally, because he was observed with exactly one of those peers at least 10 times, he had a score of 1 at $Q = 10$. This pattern of social breadth is shown in Figure 1 by counting the number of vertices (i.e., peers) at each value of Q. In comparison, Figure 4, which represents the peer interactions for Boy 2, depicts a more

Figure 4. Graphs illustrating social breadth for Boy 2 at $Q = 1$ through $Q = 20$.

Note. This target child was observed with Peer 1023 through $Q = 36$. Q is operationalized as days (e.g., the value of the function at $Q = 8$ indicates the number of peers observed interacting with a target child on at least 8 days during the semester). Male peers are identified with square vertices and female peers are identified with circular vertices. The edges connecting vertices represent connections among peers and are not considered in the present study.

extensive pattern of social breadth. At $Q = 1$, this child had a score of 17. His score at $Q = 3$ was 11 and at $Q = 10$ was 4.

Two features of social breadth scores deserve comment. First, according to the method used to define and construct the graphs, as Q (exposure) increases, social breadth scores naturally decrease—that is, as the criterion for the number of times children were seen together increases, the natural function is for there to be fewer peer interactions that meet the criterion. Thus, selectivity in peer exposure is reflected by these changing graph indices. Second, children who were observed playing together for 2 days over the course of the semester could have been observed playing together on two consecutive days or the 2 days could have been separated by several days, weeks, or even months. Thus, as Q increases, social breadth reflects more frequent interactions (greater exposure) with peers, but the length of time between interactions with the same peers is not consistent. For the purpose of this study, we are not concerned with the length of time between observations per se, and we are focused principally on the degree of exposure to peers across the semester.

Teachers' ratings of externalizing behaviors. Teachers completed several measures of classroom externalizing behavior: physical aggression, attention problems, and anger. Physical aggression and attention problems were measured using the Aggressive Behavior (25 items, sample item "This child attacks people") and Attention Problems (9 items, sample item "This child can't concentrate") subscales of the Teacher Report Form of the Child Behavior Checklist (Achenbach & Rescorla, 2000). Each item was completed using a 3-point Likert-type scale. Both scales have been shown to be reliable and valid for preschool children (Achenbach & Rescorla, 2000).

Anger was assessed using a brief subscale of the Child Behavior Questionnaire (CBQ; Goldsmith & Rothbart, 1991; Rothbart, Ahadi, & Hershey, 1994). This measure has been used extensively with young children in prior research to assess negative emotions and regulatory abilities. The items on the CBQ were completed using a 7-point Likert-type scale, with response options ranging from *extremely untrue of this child* to *extremely true of this child*. The Anger subscale consisted of 10 items (sample item was "Gets mad when provoked by other children"; $\alpha = .92$).

Results

After conducting preliminary analyses of social breadth and the externalizing measures, we tested our two hypotheses. The first hypothesis concerned whether externalizing behaviors are related to social breadth at each of several consecutive levels of Q (with lower levels of Q representing more short-lived exposure patterns and with higher levels of Q representing greater exposure patterns). The second hypothesis concerned whether externalizing behaviors were related to variations in the pattern of decline in social breadth across levels of Q.

Preliminary Analyses of Social Breadth

Social breadth could be calculated at Q values from 1 through 46 in the present sample (i.e., no child was observed to interact with the same peer on more than 46 days during the semester). However, because of limited variability at the greatest Q levels, data are presented and analyzed for social breadth scores ranging from $Q = 1$ through $Q = 15$ only. Descriptive statistics for social breadth values at $Q = 1$ through $Q = 15$ are presented in Table 1. Because the largest class size for this sample was 20 (range = 17–20), social breadth values could not exceed 19 (i.e., at most, only 19 classmates were available as peer interactants). At $Q = 1$ (e.g., children were observed together at least one time in the semester), social breadth scores ranged from a low of 4 to a high of 19, and the mean of 16.1 indicated that, on average, children interacted with almost every classmate at least once in the semester. Social breadth scores decreased as Q increased,

Table 1

Descriptive Statistics for Social Breadth Scores at Q = 1 Through Q = 15 (N = 97)

Q	Minimum	Maximum	*M*	*SD*	Skewness	Kurtosis
1	4	19	16.1	2.7	−1.4	3.3
2	0	19	13.4	4.2	−0.7	0.3
3	0	19	11.2	5.1	−0.2	−0.8
4	0	19	9.5	5.3	0.2	−1.0
5	0	19	7.8	5.1	0.4	−0.9
6	0	18	6.6	4.8	0.6	−0.6
7	0	17	5.5	4.4	0.8	−0.2
8	0	16	4.5	3.8	0.9	0.0
9	0	16	3.8	3.5	1.2	1.1
10	0	14	3.2	3.1	1.2	1.2
11	0	11	2.8	2.7	1.1	0.9
12	0	11	2.3	2.4	1.3	1.5
13	0	9	2.0	2.2	1.3	1.3
14	0	9	1.7	1.9	1.4	2.0
15	0	8	1.5	1.8	1.5	2.4

Note. Q is operationalized as days (e.g., the value of the function at $Q = 8$ indicates the number of peers observed interacting with a target child on at least 8 days during the semester).

and at $Q = 15$, the mean was 1.5. Note, however, that the maximum score of 8 suggests that some children interacted with as many as eight classmates for at least 15 days. Social breadth scores were normally distributed, and no score exceeded recommended cutoff scores of skewness = 2 or kurtosis = 7 (Curran, West, & Finch, 1996).

Social breadth scores were modestly sensitive to age-related differences among preschoolers. At $Q = 1$, age was not significantly correlated with social breadth. However at $Q = 2$ through $Q = 15$, the correlations between age and social breadth were of modest magnitude and significant at $p < .05$ or better; range was $r(97) = .21, p < .05$ to $r(97) = .31, p < .01$. There were no sex differences in social breadth scores at any level of Q. Because this sample was ethnically diverse, we also tested for ethnicity differences in social breadth, but these were not significant at any level of Q. Children who are more frequently absent from school have fewer opportunities to be observed interacting with peers. Social breadth was significantly correlated with the proportion of time that children were absent from school or unavailable (e.g., in the bathroom or napping), such that children who were absent more frequently had lower social breadth scores at $Q = 1$ through $Q = 15$; range was $r(97) = -.36$ to $r(97) = -.52$, all $ps < .001$. We also calculated the intraclass correlation (ICC) reflecting the effect of classroom differences on social breadth scores at $Q = 1$ through $Q = 15$. ICCs ranged from .40 (at $Q = 15$) to .71 (at $Q = 6$). According to Kreft (1996), ICC scores greater than .10 indicate significant within-group variance on the outcome variable. As such, there was substantial variability in breadth scores across classrooms. Thus, child age, absences/unavailability, and classroom (treated as a random effect) were entered as covariates in subsequent analyses.

Preliminary Analyses of Externalizing Variables

Table 2 provides descriptive statistics for the externalizing-related variables: physical aggression, attention problems, and anger. None of the externalizing-related variables were significantly skewed. Although there were no age or ethnicity differences in any externalizing variable, there were significant sex differences. Boys were significantly more likely to be rated higher on attention problems and anger than were girls, $ts(86, 87) = 3.01$ and 3.18, respectively, $ps < .01$. The effect sizes for these relations were in the large range. Moreover, boys were marginally higher than girls on physical aggression, $t(86) = 1.67$, $p = .10$, with a medium effect size.

Relations Between Externalizing Behaviors and Social Breadth at Each Level of Q

Using SAS (9.1) Proc Mixed, we conducted mixed model regressions to assess the relations between externalizing-related behaviors (physical aggression, attention problems, and anger) and social breadth at $Q = 1$ through $Q = 15$. For each analysis, age and school absences/unavailability were entered as fixed covariates and classroom was entered as a random covariate. Main effects for externalizing behaviors and sex were entered (with separate analyses conducted for physical aggression, attention problems, and anger due to high intercorrelations among the variables); $rs(88)$ ranged from .52 to .80, $ps < .001$. Sex differences were tested by the inclusion of an interaction term between the appropriate externalizing variable and sex. Social breadth at each value of Q was analyzed separately to test for variations in the relations between externalizing behavior and social breadth across increasing levels of Q.

None of the interaction terms with sex reached statistical significance. The interaction terms were then dropped, and the models were reestimated. Table 3 presents the results of the regression analyses for the effects on social breadth attributable to aggressive behavior, attention problems, and anger. The results indicated that the externalizing variables were unrelated to social breadth at low levels of Q. However, at medium to high levels of Q, physical

Note. Degrees of freedom are 1, 78 for analyses with physical aggression and attention problems and 1, 79 for analyses with anger.
$^{*}p < .05$. $^{**}p < .01$.

aggression, attention problems, and anger were negatively related to social breadth. Specifically, for physical aggression, statistically significant effects were found for *Q* = 9 and above (with a marginal effect at $p = .06$ when *Q* = 11). Significant effects were obtained for attention problems at *Q* values greater than 5 (with a marginal effect at $p = .08$ when *Q* = 15), and for anger at *Q* values greater than 7 (with marginal effects of *p*s = .12 and .09 when *Q*s = 11 and 12, respectively). Effect sizes for statistically significant effects were generally in the medium range, ranging from δs = .32 to .42 for physical aggression, from δs = .31 to .45 for attention problems, and from δs = .30 to −.37 for anger. Additionally, the term for school absence was significant at $p < .001$ in each analysis, but the age and sex terms did not reach statistical significance in any analysis. Finally, it is worth noting that classroom level effects were strong, and the average ICC was .66.

Relations Between Externalizing Behaviors and Patterns of Decline in Social Breadth

In the next set of analyses, we considered how patterns of decline in social breadth across levels of exposure (i.e., *Q*) related to externalizing behaviors. Classification techniques, such as cluster analysis, are inherently useful for grouping individuals according to various patterns across variables, and such analytic tools are well suited to graph theory in general and social network analysis in particular (see Arabie & Hubert, 1992, for a review). Typically in developmental science, measures of different constructs taken at one point in time are cluster analyzed to identify subgroups that vary along a number of dimensions. However, in prior research, cluster analysis has also been shown to be a valuable tool for differentiating the profiles of subgroups that differ on a construct across time (Gorman-Smith, Tolan, Loeber, & Henry, 1998; Hirsch & DuBois, 1991). In this case, we adapted this approach by cluster analyzing social breadth scores across increasing *Q* values. It should be noted that the social breadth scores at each level of *Q* were related, such that Q_i equaled Q_{i+1} plus an additional term with random variability. Although cluster analyzing such mathematically dependent variables is novel in the developmental sciences, it does not violate the assumptions of cluster analysis nor is it without precedent in other disciplines, such as biology (Toh & Horimoto, 2002). In the present study, we first used a hierarchical clustering procedure to identify distinct subgroups of children with differing patterns of decline in social breadth scores as exposure increased from *Q* = 1 to *Q* = 15. We followed these analyses with mixed model analyses to assess the relations between externalizing behaviors and variations in patterns of the decline in social breadth.

Cluster analysis of decline in social breadth. We used the average linkage clustering method, which creates homogeneous clusters by minimizing the mean distance between each case and all other cases in the cluster. Squared Euclidean distances were used as the measure of dissimilarity (Milligan, 1996). Prior to cluster analysis, social breadth scores at $Q = 1$ through $Q = 15$ were equated by dividing by their respective ranges. This method is recommended by Milligan and Cooper (1988) and is preferable to standardization of variables because it places variables on the same scale without diminishing differences in variances. Examination of the dendrogram and agglomeration coefficients indicated that three groups could be differentiated. The resulting three-cluster solution was validated by conducting a confirmatory cluster analysis (Fisher & Ransom, 1995). Specifically, we used the *k*-means clustering method (MacQueen, 1967) to conduct a nonhierarchical cluster analysis specifying three groups. Because deriving the clusters' initial centroids randomly may create distortions in the classification scheme in a nonhierarchical cluster analysis (Milligan & Sokol, 1980), we ran the nonhierarchical cluster analysis twice, once without specifying start values and a second time in which we entered start values based on the final cluster centroids that were produced using a third clustering procedure—Ward's (1963) clustering method. The results of both nonhierarchical analyses were identical. We then compared the original cluster solution with the confirmatory cluster solution using the kappa coefficient, $\kappa = .64$, which is in the good range (i.e., $.60 < \kappa < .80$; Landis & Koch, 1977).

The resulting three-cluster solution is depicted in Figure 5. The cluster groups could be differentiated from one another on the basis of mean scores on social breadth, as well as differences in the curve of the decay patterns (e.g., slopes) and are labeled according to mean social breadth scores as *high* (25% of cases), *medium* (14% of cases), and *low* (61% of cases). To validate the results of the cluster analysis, we conducted a multivariate analysis of variance, comparing cluster groups with social breadth scores at *Q* values of 1–15. We obtained a significant multivariate effect, $F(30, 160) = 10.28$, $p < .001$, $\eta^2 = .66$; significant univariate effects were obtained for social breadth scores at each level of *Q*, $Fs(2, 94)$ ranged from 26.23 to 192.74, all $ps < .001$; η^2 estimates ranged from .36 to .80. Post hoc analyses indicated that at $Q = 1$, there were no significant differences in social breadth scores between the high and medium groups, but children in both the high and medium groups interacted with significantly more peers than those in the low group, $ps < .001$. At subsequent levels of *Q* (2 through 15), children in the high group interacted with significantly more peers (i.e., had higher social breadth scores) than children in both the medium and low groups, and children in the medium group interacted with significantly more peers (i.e., had higher social breadth scores) than children in the low group, all $ps < .05$.

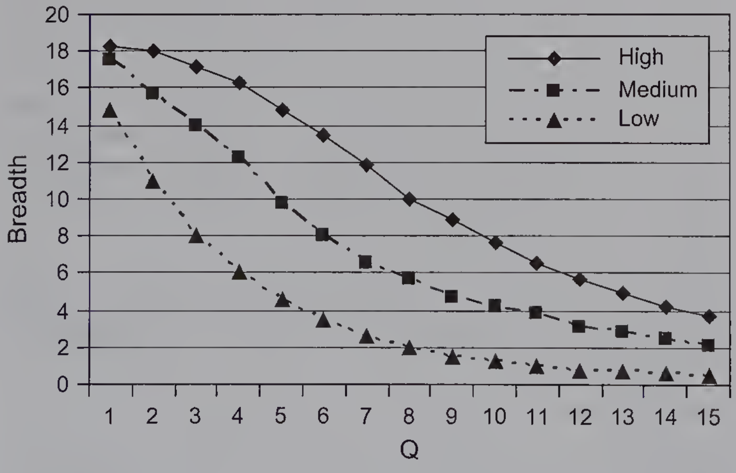

Figure 5. Social breadth scores for three cluster groups at $Q = 1$ through $Q = 15$.
Note. *Q* is operationalized as days (e.g., the value of the function at $Q = 8$ indicates the number of peers observed interacting with a target child on at least 8 days during the semester).

To illustrate the variations in the curves, we calculated the decay rates for each group using an exponential function. We found that an exponential function best fit the overall pattern of the data. Fit indices were R^2s = .98, .99, and .99, for the high, medium, and low groups, respectively. The decay formula for the high group was $y = 25.115e^{-0.1224x}$. This indicates that the estimated intercept for this group was 25.12 (where the intercept reflects the estimated value of social breadth at $Q = 0$), and the estimated decay rate was .12. The decay formula for the medium group was $y = 20.894e^{-0.1558x}$. Thus, the estimated intercept for this group was 20.89 and the estimated decay rate was .16. Finally, the decay formula for the low group was $y = 16.311e^{-0.2485x}$, indicating that the estimated intercept for this group was 16.31 and the estimated decay rate was .25.

Finally, we considered whether the children in the high, medium, and low groups differed on either sex or age. There were no significant sex differences. However, we did obtain a significant effect for age, $F(2, 94) = 4.50$, $p < .05$, $\eta^2 = .09$. Younger children were significantly more likely to be in the low group than in either the medium or high groups, although the effect size for this relation was weak.

Relations between social breadth clusters and externalizing behaviors. We conducted mixed model analyses of variance to estimate the relations between the patterns of decline in social breadth that we obtained from the cluster analyses and externalizing behaviors. Age and school absence/unavailability were controlled as fixed covariates and classroom was controlled as a random effect. Additionally, a main effect term for sex and interaction terms representing the cluster group by sex effect were entered. Externalizing behavior variables served as criterion variables in separate analyses. Significant overall effects were followed with Tukey post hoc tests with the Kramer adjustment for unequal cell sizes (Tukey, 1973).

None of the interaction terms with sex were significant. Thus, the interaction terms were deleted, and the models were reestimated. The mean scores (adjusted for age, sex, school absences, and classroom) on the externalizing-related variables for each cluster group are presented in Table 4. The overall effect of social breadth cluster group on physical aggression approached, but did not reach, statistical significance, $F(2, 77) = 2.86$, $p = .06$. For attention problems, the overall effect of social breadth cluster group was statistically significant, $F(2, 77) = 3.11$, $p = .05$. Children in the medium group had significantly higher scores on attention problems than those in the high group, $t(77) = 2.47$, $p < .05$. A significant overall effect was also obtained for anger, $F(2, 78) = 5.81$, $p < .01$. Again, we obtained a significant difference between children in the medium group and those in the high group, with children in the medium group rated as angrier than children in the high group, $t(78) = 2.49$, $p < .05$. Additionally, we also found that children in the low group were significantly more angry than children in the high group, $t(78) = 3.28$, $p < .01$. Effect sizes were in the small range for attention problems ($\delta = .27$) and in the medium range for anger ($\delta = .36$). The following fixed covariates also reached statistical significance: sex (for models with attention problems and anger) at $p < .01$ and school absence/unavailability (for models with physical aggression and anger) at $p < .05$. The ICCs suggested small to modest classroom effects for models with physical aggression and attention problems (the ICCs were .16 and .32, respectively) but no meaningful classroom effects for the model with anger (the ICC was .00).

Table 4
Mean Scores on Externalizing-Related Behaviors for Social Breadth Cluster Groups

	Low	Medium	High
Physical aggression	7.5 (2.0)	9.5 (3.1)	2.0 (2.9)
Attention problems	2.6 (1.0)	4.2 $(1.3)_a$	1.3 $(1.3)_a$
Anger	4.2 $(0.2)_a$	4.2 $(0.4)_b$	3.1 $(0.3)_{ab}$

Note. Means are adjusted for age, sex, school absences, and classroom. Standard errors are presented in parentheses. Means in the same row that share lowercase subscript letters are significantly different at $p < .05$.

Discussion

In this study, we used a new quantitative procedure, the *Q*-connectivity method, which builds on traditional social network methods by using repeated assessments of children's peer interactions to characterize individual children's social networks. We used this method to assess preschoolers' social breadth as a function of their exposure to peers over time, and we demonstrated relations between social breadth and three indices of externalizing behaviors—physical aggression, attention problems, and anger.

Externalizing Behavior and Social Breadth

We examined the relations between externalizing behavior and the drop-off in social breadth that occurs in relation to increasing exposure to peer interaction (e.g., value of *Q*). We considered drop-off in two ways: *decreases in social breadth* scores across *Q* values and *variations in patterns of decline* across *Q* values. Analyses of the relations between externalizing behaviors and social breadth scores across *Q* values demonstrated that several aspects of externalizing behavior—physical aggression, attention problems, and anger—were negatively related to social breadth. However, these relations only emerged at moderate to high levels of *Q*—that is, moderate to high frequency of exposure to the same peers. These relations were not evident at lower levels of exposure. The overall pattern of findings was robust along two important dimensions. First, the findings were consistent for behavioral (physical aggression), attentional (attention problems), and emotional (anger) indices of externalizing behavior, suggesting consistency across constructs. Second, the consistent lack of effects at lower levels of *Q* combined with the significant findings at moderate to higher levels of *Q* (with the exception of a few instances in which the effects approached, but fell just short of reaching, statistical significance; these were $Q = 11$ for physical aggression, $Q = 15$ for attention problems, and $Qs = 11$ and 12 for anger) suggests consistency in the patterns of relations as exposure to peers increases. Moreover, the obtained effect sizes in the medium range suggest that these are not trivial findings.

Analyses of patterns of decline in social breadth suggested that three groups of children could be differentiated, with group trajectories defined according to both intercept and curve. Children who exhibited a pattern of social breadth characterized by initially high social breadth scores (i.e., a high intercept) and a modestly declining curve tended to have relatively high scores on attention problems and anger, although the relation with physical aggression did not quite reach statistical significance. In addition, children who exhibited a pattern characterized by initially low social breadth scores and a steeply declining curve tended to have relatively high scores on anger but not on physical aggression or attention problems. In contrast, those children who exhibited a pattern of social breadth characterized by initially high scores and a slowly declining curve were unlikely to exhibit physical aggression, attention problems, or anger.

Taken together, these findings suggest that externalizing preschoolers, like their classmates, may play with most peers in the class on one or a few occasions. However, their exposure to peers moderately to rapidly became selective as they began to interact with a relatively small number of peers. Of particular interest is the question of what peer processes underlie the drop-off in peer exposure for externalizing children, keeping in mind that these processes may vary depending on the type of peer with which an externalizing child is interacting. Either of two social processes may be at play here. On the one hand, if externalizing children prefer playing with peers with similar levels of aggression, they may have few peers to choose from in a class. Furthermore, playing with peers who are not similar on this dimension of behavior may not be enjoyable; thus, exposure to nonaggressive peers may drop off quickly. Thus, on the one hand, this effect may be driven by externalizing children themselves. On the other hand, such children may be actively disliked by the larger peer group (Snyder et al., 1997). Thus, they might have fewer opportunities to engage with mainstream peers as their classmates become sensitized to their negative behaviors and actively reject them (Olson, 1992).

It is likely that both processes may contribute to the drop-off that we found in this study. However, these processes may be differentially weighted or they may operate differently depending on the type of peer—internalizing versus socially competent versus externalizing. For example, one recent study mapped the dynamic nature of externalizing children's tendencies to interact with externalizing, socially competent, and internalizing peer partners (Martin et al., 2005). Findings from this study demonstrated that interactions with peers who were themselves externalizing were attractor states for young externalizing boys and girls (providing evidence for behavioral homophily) and, to a somewhat lesser degree, interactions with socially competent peers were also attractor states. However, externalizing children rarely interacted with internalizing peers. Perhaps the interactions with internalizing peers are the most ephemeral for young externalizing children (dropping off quickly), whereas the interactions with other externalizing children are most likely to be repeated. Presumably, then, internalizing peers are those who only show up at low levels of exposure (e.g., $Q = 1$ or 2). Socially competent peer partners might show up at moderate levels of exposure (e.g., moderate Q graphs), and those peers in the highest Q graphs are likely to be the externalizing ones. Thus, homophily and selectivity might underlie social breadth patterns in relation to peers who are also externalizing, but rejection might explain the drop-off in social breadth for peers who are socially competent. Future research that tests these hypotheses with a fine-grained analysis of the behaviors that are emitted by both externalizing children and their peers during interactions could shed more light on this issue. Understanding these issues can provide insight into the social trajectories on which young externalizing children find themselves; this is necessary to attempts to intervene in this behavioral pathway.

Developmental–Contextual Perspective on Social Breadth

The primary research findings should be interpreted in light of the developmental–contextual effects that were (and were not) obtained. First, there were neither main effects nor interaction effects of sex on social breadth, indicating that boys and girls had similar social structures, at least with respect to the breadth of their peer relationships and at least with the sample of young children that we used. There has been some question about the extent to which there are sex differences in the size of children's peer networks. Studies on kindergarten-age and older children have suggested that boys have larger social networks than do girls (Ruble et al., 2006). Moreover, Waldrop and Halverson (1975) found that 7-year-old boys had more extensive peer relationships than did girls. Among younger children, however, the findings are mixed, with some studies suggesting that there are sex differences in the size of social networks and others finding no differences (Ruble et al., 2006). This may reflect a developmental process; thus, we speculate that sex differences in social breadth would be apparent among older children.

Moreover, the lack of sex effect in the present study should be seen as contributing to recent efforts to explore sex differences in externalizing behaviors and the social correlates of externalizing behavior. Consistent with the larger body of research on physical aggression, in the present study, boys were rated as more externalizing than girls, that is, boys were rated by teachers as significantly more angry and as displaying significantly more attention problems, although the sex difference in physical aggression, favoring boys, approached, but did not reach, statistical significance. This finding is generally robust, as opposed to findings regarding sex differences in relational forms of aggression, which tend to be mixed, even among young children (Crick, Casas, & Mosher, 1997; Hart, Nelson, Robinson, Olsen, & McNeilly-Choque, 1998; Underwood, Galen, & Paquette, 2001). Given the inherently social nature of relational aggression, it would be useful to replicate this research using measures of relational aggression, as the patterns may vary. Moreover, this study speaks to a small, but important, body of literature that has considered whether there are sex differences in the quality of peer relations for aggressive children. Most of the extant research in this area has focused on peer rejection, and the findings have been mixed, with some studies showing sex differences in the extent to which externalizing children are rejected and others showing no sex differences (Zimmer-Gembeck et al., 2005). The lack of significant sex effects in the present study may indicate that the general structures of peer interactions for young externalizing boys and girls are quite similar despite any variations in involvement in physical forms of aggression. More research on this issue is clearly needed.

The present findings also support the idea that social breadth may vary with age. In the 3- to 5-year-old children in the present study, we found age-related differences in social breadth. This developmental period is an important one from a social interactional perspective. At this age, children are making the shift from playing alone or alongside peers to playing with peers (Rubin & Coplan, 1998). It was no surprise, then, that younger children in our sample had lower social breadth than did older children and that they demonstrated the steepest drop-off in social breadth. This may typify a normative social developmental process in early childhood that is marked by the movement from solitary play behaviors toward increasing engagement in social play with age and social experience. Recall that social breadth was measured in the fall semester. It is possible that assessments of social breadth in the spring semester of preschool (after children had several months of experience in peer group settings) would identify fewer children in the low group. A question for future research is whether social breadth continues to show age-related variations as children get older; perhaps age differences would be seen as children reach important developmental transitions, such as the transition from elementary to middle school or the transition from engaging in same-sex peer groups to greater involvement with members of the other sex that occurs in adolescence.

From a contextual perspective, we obtained relatively strong classroom effects, suggesting that aspects of the classroom environment contribute to children's socialization patterns. Classroom characteristics may affect social breadth in numerous ways. Perhaps the aggregation of particular types of peers (e.g., classrooms with larger numbers of externalizing children) creates variations in socialization patterns. As demonstrated by Stormshak et al. (1999), social preference scores in first-grade classrooms depended upon the extent to which classmates were aggressive, with aggressive children having higher social preference scores in aggressive classrooms and lower social preference scores in nonaggressive classrooms. Additionally, we have previously reported classroom level effects on patterns of peer victimization in preschool classrooms using a different sample of young children (Hanish, Ryan, Martin, & Fabes, 2005). Alternatively, teachers' behaviors and child management styles may create different patterns of socialization from one classroom to another. For instance, the extent to which teachers take an active role in structuring children's peer relationships may influence socialization patterns (Howes, Hamilton, & Matheson, 1994). We did not have a large enough sample of classrooms to adequately test for classroom effects in this study. Thus, future research that dissects the role of classrooms is needed to better understand this contextual contributor to social breadth.

Future Directions for the Use of the Q-*Connectivity Method*

In the present study, we did not directly consider issues related to peer contagion processes, although the findings regarding social breadth set the stage for a process-oriented analysis. Recent evidence suggests that, even in early childhood, the opportunity exists for both selection and influence processes to operate with regard to the spread of aggressive behaviors (Hanish, Martin, et al., 2005). Little is known about the extent to which weak ties with peers (e.g., brief encounters, acquaintanceships) as well as strong ties with peers (e.g., mutual friendships) are determined by peer selection processes and about the extent to which each enables peer socialization along externalizing dimensions. However, one recent study with adolescents suggests that there is value in considering the extent to which weak social ties influence decisions to engage in delinquent behaviors (Bauman, Faris, Ennett, Hussong, & Foshee, 2007). Building on this idea, future studies that explore externalizing children's social breadth in more depth, for instance, with regard to the valence of the interactions (e.g., Do the patterns of social breadth depend on the extent to which peer interactions are negative or positive?) or the characteristics of peers (e.g., Is social breadth moderated by peers' characteristics?) are possible using the *Q*-connectivity method and would likely be fruitful.

An additional avenue for future research has to do with the conceptual and analytic approach to the time dimension. One of the most interesting and important features of the *Q*-connectivity method is that it incorporates time in a direct way. There are numerous ways to reflect time with this method. Some of these include conducting frequency counts over some period of time and calculating trajectories over *Q*, as we did here. An example of another use of the time component involves creating moving windows that can assess variations in peer structures across time, which would allow a more fine-grained assessment of the time between contacts with various peers. Although this issue was not central to the theme and focus of the present article, it is of great interest to a number of important developmental questions. For instance, one might hypothesize that frequent contacts with a peer that occur at the beginning of the school year but that diminish over time might have a different developmental meaning than an equal number of contacts with a peer that are spaced out over the academic semester or year. Future research that builds on the present study by considering time in alternative ways would lend insights into the development of peer relationships and contribute to the small, but growing, compendium of dynamic methods for studying peer relations (e.g., state space grids, Granic & Patterson, 2006; Simulation Investigation for Empirical Network, Snijders, 2005).

One unique feature of this study was the use of the *Q*-connectivity method to map each individual child's social landscape and how this changed across differing levels of exposure to peers. We focused only on one parameter of *Q*-connectivity, namely social breadth. Although it is beyond the scope of the current paper, the *Q*-connectivity method also has the potential to offer a host of informative measures of interactional patterns; connectivity, density, maximum value of *Q*, dyadicity, and a variety of other social network measures across *Q* are examples of just a few measures that can be calculated using this method. *Q*-connectivity analyses also may be undertaken to reveal latent structures in social interactional patterns. Additionally, the use of graphics as a data visualization tool for examining social interactional patterns over time may make a powerful contribution and may open up new lines of systemic research (Legrand, 2002). The introduction of the *Q*-connectivity method allows for an expanded ability to assess peer interactions and thus has the potential to inform researchers about peer socialization processes. Thus, the *Q*-connectivity method has relevance to issues such as understanding the formation, evolution, and dissolution of peer relationships, peer selection effects, and peer influence processes.

The Effects of Background Television on the Toy Play Behavior of Very Young Children

Marie Evans Schmidt, Tiffany A. Pempek, Heather L. Kirkorian, Anne Frankenfield Lund, and Daniel R. Anderson
University of Massachusetts at Amherst

This experiment tests the hypothesis that background, adult television is a disruptive influence on very young children's behavior. Fifty 12-, 24-, and 36-month-olds played with a variety of toys for 1 hr. For half of the hour, a game show played in the background on a monaural TV set. During the other half hour, the TV was off. The children looked at the TV for only a few seconds at a time and less than once per minute. Nevertheless, background TV significantly reduced toy play episode length as well as focused attention during play. Thus, background television disrupts very young children's play behavior even when they pay little overt attention to it. These findings have implications for subsequent cognitive development.

Consider a 2-year-old child playing with toys in the living room. The television is playing a program designed for adult viewers. Mother is in the kitchen making dinner while listening to the TV. The child intermittently looks at the television for brief periods of time. Is television having an effect on the child? In this article, we test the hypothesis that background television is a disruptive influence on very young children's behavior, specifically object play.

Prior research indicates that young children pay little attention to television that they cannot comprehend (e.g., Anderson, Lorch, Field, & Sanders, 1981) and little attention to adult TV programs in general (Schmitt, Anderson, & Collins, 1999). Thus, an adult television program is essentially in the background as the child plays with toys or engages in social interactions. Here, we adopt the term *background television* to refer to adult content that is largely incomprehensible to a very young child and to which they ordinarily pay little cumulative attention (see Anderson & Evans, 2001). Nevertheless, as a dynamically varying audiovisual distraction, background television may interfere with the ability of very young children to sustain an activity in a focused and organized manner.

The American Academy of Pediatrics, Committee on Public Education (1999) recommends no screen media exposure for children aged 2 years and younger. Nevertheless, nearly 75% of parents of very young children say that television is on "about half of the time" or more, even if no one is watching (Rideout & Hamel, 2006; Rideout, Vandewater, & Wartella, 2003). There is substantial opportunity in these homes for background television to have a chronic disruptive impact on very young children's behavior.

It should be emphasized that the present study is concerned with the impact of adult programming that is in the background from the perspective of the child. Very young children certainly spend time watching programs made for them. Studies that did not specifically assess background TV have found that very young children watch from 1 to 3 hr a day, on average (Anderson, Lorch, Collins, Field, & Nathan, 1986; Carew, 1980; Clarke-Stewart, 1973; Gottfried, 1984; Lemish, 1987; Rideout & Hamel, 2006; Rideout et al., 2003; Zimmerman, Christakis, & Meltzoff, 2007), although there are large percentages of children whose parents claim they do not watch any TV (Certain & Kahn, 2002; Christakis, Zimmerman, DiGiuseppe, & McCarty, 2004; Rideout et al., 2003; Woodard, 2000).

Marie Evans Schmidt is now at the Center on Media and Child Health, Children's Hospital, Boston, MA.

Tiffany A. Pempek is now at Georgetown University in Washington, DC.

This research is based in part on a University of Massachusetts doctoral dissertation by Marie Evans Schmidt. Aspects of this research were presented at the meetings of the Society for Research in Child Development and at the meetings of the International Conference on Infant Studies. This research was supported by grants from the National Science Foundation (BCS-0111811 and BCS-0519197). Findings and opinions expressed in this article do not reflect endorsement by the National Science Foundation. We wish to acknowledge the videotape coders for this project: Amy Fuller, Sean Kennedy, Lauren Murphy, Rae Gallagher, Carolynn Laurenza, David Massuda, Rebecca Edwards, Jill Rosenbaum, Kate Decker, Emily Duclos, Erica Gentuso, Kristian Lundberg, Alexis Lauricella, and Angie Naniot. We also wish to acknowledge Aline Sayer and Arnold Well for statistical consultation.

In the only study to specifically consider background TV, Pierroutsakos, Hanna, Self, Lewis, and Brewer (2004) asked 100 upper-middle-class parents to keep diaries of their 2.5- to 24-month-old infants' TV exposure. The children were exposed to an average of 120 min of TV each day; 49% of that exposure was to adult and preteen programming. It is likely that a broad survey would reveal that a large percentage of very young children are exposed to much more background TV than found by Pierroutsakos et al. insofar as in-home automated monitoring of TV use by Nielsen Media Research indicates that the average American home has a TV set in use more than 8 hr a day (Gertner, 2005).

Effects of Television on Very Young Children

There is very little experimental research on the effects of television on infants and toddlers and no direct research on the effects of background exposure. The studies that have examined long-term effects of early television exposure are correlational and do not account for content of the programs, thus combining exposure to age-appropriate and background television. Television exposure for children aged 30 months and younger is associated with poorer cognitive and language development (Carew, 1980; Gottfried, 1984; Nelson, 1973; Wachs, 1985; Wachs & Gandour, 1983; Wachs & Gruen, 1982; Zimmerman & Christakis, 2005). One study reported that language development depended on which child-directed programs were regularly watched, with some programs positively associated with language development and other programs negatively associated (Linebarger & Walker, 2005).

Christakis et al. (2004) reanalyzed data from the 1980s National Longitudinal Survey of Youth to determine if there was a relationship between early TV viewing and later attention disorders. Parents' estimates of their children's TV viewing at 18 and 42 months were positively associated with parental reports of attention disorder symptoms at age 7 after a variety of covariates were statistically controlled. An analogous study in Denmark, however, failed to find a significant relationship, although the trend was in the same direction (Obel et al., 2004). Television viewing by older preschoolers does not predict attention disorder symptoms (Stevens & Mulsow, 2006).

Several studies have revealed that the level of ambient background noise in the home and household chaos are negatively related to cognitive development in the first 5 years of life (Gottfried, 1984; Wachs, 1985, 1986; Wachs & Gandour, 1983). Because television is a major contributor to the level of ambient noise in these studies, it may play a disruptive role, as hypothesized. Nevertheless, the studies cited above that found negative outcomes associated with television exposure do not allow causal relationships with television to be conclusively inferred.

Background Television and Toy Play

Based on videotapes of family TV viewing recorded in homes, Schmitt, Woolf, and Anderson (2003) reported that 2-year-olds played with toys 32% of their time spent with television. The present study, by experimentally manipulating the presence of background television, is designed to determine whether television is a proximal disruptive influence on the organization of very young children's behavior, specifically toy play. Television may have such an influence by initiating repeated orienting reactions to the visual and auditory changes that frequently occur on commercial television. Television may also be viewed as competing for cognitive resources necessary to instantiate and execute play schemes (cf. Armstrong & Greenberg, 1990). In addition, as a source of environmental noise, background television may have a general disruptive effect that has been observed on children in noisy environments (Hygge, Evans, & Bullinger, 2002; Wachs, 1986).

Virtually every theory of child development hypothesizes that play is related to healthy cognitive and social development (e.g., Piaget, 1962). During play, children refine motor skills, explore the physical properties of objects, learn principles of cause and effect, and engage in means – ends problem solving (Power, 2000). Pretend play, in particular, helps children develop representational abilities as well as experiment with social roles (Bretherton, 1984; Power, 2000). If background television disrupts young children's play, chronic exposure to background television may at least partially be a cause of the negative relationship between early exposure to television and cognitive development.

In this research, we examine play maturity, play episode length, and focused attention during play. With respect to play maturity, we use a scale based on research by Belsky and Most (1981). The logic of the scale extends from numerous studies that reveal a developmental sequence of toy play behaviors. As development proceeds from early infancy, visually guided manipulation and object-appropriate behaviors increase and become more symbolic and complex (Belsky & Most, 1981; McCall, 1974).

Play episode length refers to the time that elapses from the point at which the child comes into contact with a toy until the child ceases active play with that toy (Choi & Anderson, 1991). As children mature, play episode length increases (Malone, 1997; Ruff & Lawson, 1990), probably reflecting more sequentially complex play schemes as well as an ability to sustain attention. Short play episode length is a predictor of attention deficit disorders and other developmental problems (e.g., Faden & Graubard, 2000; Handen, McAuliffe, Janosky, Feldman, & Breaux, 1998; Malone, 1997).

The intensity of attentional engagement may vary during play episodes. The term *focused attention* has been used to designate activity during which "attention is directed more or less exclusively to one target or task and not divided or shared between targets or tasks" (Ruff & Rothbart, 1996, p. 111). As motivation and attention are linked (Derryberry & Tucker, 1990), focused attention usually results when a target activity is highly motivating and is made possible by inhibiting responses to all but the object or task (Ruff, Capozzoli, & Saltarelli, 1996).

Infants and toddlers are capable of focused attention, although the underlying processes supporting attention change substantially during the first 3 years. Ruff and Rothbart (1996) describe the development of two different attentional systems in very young children. The orienting/investigative system, dominant for the 1st year of life, is primarily responsive to novelty, meaning attention in young infants is governed by the salient perceptual features of environmental stimuli. Ruff, Saltarelli, Capozzoli, and Dubiner (1992) found that focused attention in 5- to 12-month-old infants was greatest for novel objects. After 2–3 min of exposure to the same object, however, episodes of focused attention were terminated. Focused attention episodes in infancy are thus usually short, occurring intermittently with other exploratory actions (e.g., banging or mouthing).

The second system of attention, that of higher level control, appears at the end of the 1st year as the prefrontal cortex matures. Ruff and Rothbart (1996) hypothesize that the second system facilitates or inhibits the orienting/investigative system as children develop the cognitive ability to formulate plans or goals. These plans can prevent habituation by facilitating sustained attention after objects are no longer novel. As children develop cognitively and acquire language, their goals can become more sophisticated leading to longer episodes of focused attention, particularly during play. Consistent with this theory, focused attention during play increases with age (Ruff & Capozzoli, 2003; Ruff & Lawson, 1990). With respect to the present research, because very young children have poorly developed higher level control, it is expected that they have a poor ability to filter irrelevant stimuli as they engage in object play.

In light of research on attention development, background TV should disrupt sustained and focused attention during play. This hypothesized disruption occurs because TV repeatedly elicits orienting responses (ORs), thereby drawing attention away from the play. Physiologically, the OR is characterized by heart rate decrease, dilation of blood vessels that lead to the brain, and constriction of blood vessels that lead to the major muscle groups, along with visual orientation in the direction of the stimulation that elicited the OR. The cardiovascular changes are generally thought to reflect shifts in blood supply to the brain in service of alert investigation of novel stimuli. Consistent with previous OR research, Reeves, Thorson, and Schleuder (1986) found decreases in alpha waves that were time locked to formal features (e.g., cuts, sudden camera changes, movement, sound effects) on electroencephalographic (EEG) recordings of adults watching television. Richards and his colleagues (Richards & Casey, 1992; Richards & Cronise, 2000; Richards & Gibson, 1997) also found evidence of the OR produced by television in studies of heart rate in infants and toddlers.

A child who orients to a TV screen may suspend play in order to attend to television. Because there is a visual or auditory change on TV approximately every 6 s (Schmitt et al., 1999), background television could disrupt children's play many times over the course of a play session. A few studies suggest that brief interruptions can terminate young children's ongoing activities. DiLalla and Watson (1988) observed 2.5- to 6.5-year-old children's reactions to three experimenter-initiated interruptions to an ongoing fantasy play sequence. Older children were better able to respond to interruptions without disrupting their subsequent play. The 3-year-olds were unable, however, to return to the play episode without experimenter prompts. Furthermore, if the play resumed, it was less intense. To the extent that it has a disruptive influence, background television may prevent young children from returning to play at the same level of cognitive sophistication, if at all.

It is possible that television does not have these disruptive effects insofar as Ruff and Capozzoli (2003) found that an intermittent brief distractor did not reduce focused attention during toy play in very young children. This may have happened because the children became progressively less distractible over the 12-min course of the play session, suggesting that they habituated to the distractor. However, television, as a complex, continuously varying distractor, may have more substantial effects and may prove to be resistant to habituation.

In the present research, 12-, 24-, and 36-month-old children were observed playing with toys for 1 hr. Children in this age range are just beginning complex and symbolic play and have poorly developed control over focused and sustained attention (Ruff & Rothbart, 1996). For half the time, a TV set played the television program *Jeopardy!* with commercials; for the other half, the TV set was off. The children were videotaped, and observers subsequently coded the tapes for looking at television, length of play episodes, length of focused attention during play episodes, and maturity of play. We hypothesized that background television would disrupt the children's toy play, shortening the length of play episodes and reducing the percent of play that was focused. We also hypothesized that background television would reduce the maturity of children's play.

Unlike prior research on television's impact, we focused specifically on background TV insofar as *Jeopardy!*, a game show directed at adults, should be nearly incomprehensible to such young children. Because many children are exposed to background television in the home and some studies suggest such exposure may negatively influence cognitive and language development, this study is a first step toward understanding one mechanism by which television may affect development.

Method

Participants

Fifty children (1 Black, 2 Hispanic, and the remainder White), 17 (9 girls) 12-month-olds, 16 (8 girls) 24-month-olds, and 17 (9 girls) 36-month-olds, were randomly assigned to either the "TV first" or the "TV second" order with the constraint that half were assigned to each. All children were within 1 month of their first, second, or third birthdays. Seventy-eight percent of children had a participating caregiver whose educational level could be classified as "some college" or higher, with 60% having completed college and 12% having attained a graduate degree.

In general, these ages (12, 24, or 36 months) were chosen because a minimal amount of research has been conducted on the impact of television on very young children. More specifically, the 36-month-old group was chosen because this age overlaps with the youngest ages used in some previous work on children and television. The two younger groups were chosen because they were young enough to ensure that the program used in this study would, in fact, be background television for them insofar as children pay little attention to content that they do not understand (Anderson et al., 1981).

Potential participants were identified through state birth records. Children were recruited by means of a letter describing the study to parents and a follow-up telephone call requesting participation. The only selection criterion was that children had no parent-identified visual or hearing impairments. No participants were excluded based on this criterion.

Materials and Setting

Two rooms were used: a playroom (4.27 × 3.81 m) and an adjoining observation room separated by a one-way mirror. The playroom was furnished with an armchair, end table, toy chest, small rug, floor pillow, credenza, VCR, and 53.30-cm (21 in., diagonally measured) television set. The toy chest was open shelved and held a variety of age-appropriate toys representative of a standard toy set (e.g., McCune-Nicholich & Fenson, 1984). Pilot research indicated that no one toy in the set was overwhelmingly popular. A variety of current magazines and a newspaper were placed on the end table within reach of the armchair.

During the television session, the VCR played an episode of *Jeopardy!*, a TV game show produced for adult audiences, including the commercials that appeared with the show at the time of airing. The experimenter could control the TV and VCR from the observation room using remote control devices. At the position most frequently occupied by children as they played with toys, the TV screen subtended a visual angle of 17° horizontally. At that position, the audio volume (preset by the experimenter) at head level of a typical 2-year-old child averaged 57dB (C weighting over ten 200-ms samples), about the level of typical human speech.

Two digital video (DV) cameras were used to record the child's behavior. One DV camera, located in the playroom, was hidden in a shoebox covered with black cloth on the floor under the credenza. The other DV camera was mounted on a tripod in the observation room. The two cameras were connected to a DV mini-cassette recorder in the observation room via a switcher. Two separate monitors were also attached to the switcher allowing the experimenter to simultaneously view the perspectives of both cameras. The experimenter could thus choose at any moment which camera captured the best image of the child. An omnidirectional microphone connected to the VCR hung from the ceiling in the playroom.

Procedure

Upon entering the playroom, the children were allowed to become familiar with the toys while the experimenter explained the procedure to the parents. Once written informed consent was obtained, the experimenter left the playroom for the remainder of the session. From the observation room, the experimenter immediately began videotaping the child in the playroom. In the TV first order, the experimenter remotely started the television program as soon as video recording had commenced. When the program ended, after approximately 30 min, the experimenter turned off the television from the observation room and continued to videotape for an additional 30 min without background TV. In the TV second order, the TV remained off for the first 30 min after which the experimenter turned on the TV and VCR with the remote control.

The focus of the present experiment was on background television's influence on children's solitary play. Consequently, parents were asked not to initiate play with their child or to actively encourage their child to play with any particular toy. The experimenter suggested the parents watch TV or read magazines unless their children became fussy or explicitly demanded their attention. The parents were also asked to fill out a questionnaire about their children's media use. The children were free to play with the toys or watch TV for the duration of the hour.

Coding

Videotapes were coded with a computer using the tape-logging utility of the video-editing program, Adobe Premiere. A research assistant watching the videotape, having identified the onset of a specified behavior according to a detailed set of coding instructions, pressed an appropriate key. The computer stored the identity and the video frame number of the event. The research assistant then advanced the tape at any desired speed until the behavior was judged to have ended and pressed an appropriate key. The frame number of the end point was thus stored. In this manner, the temporal onsets and offsets of the behavior stream were recorded.

Coding proceeded in four passes. The first pass recorded the onsets and offsets of children's looks at the television screen. A look began when a child's eyes oriented to the screen and ended when the child looked away (for details, see Anderson & Levin, 1976).

The second pass recorded the onsets and offsets of play episodes. The coding used a procedure developed by Choi and Anderson (1991). An onset was defined as the frame in which a child touches a toy with which the child subsequently plays. An offset is the frame where a child stops actively playing with the toy, even if passive contact is maintained. Simultaneous contact with more than one toy constituted a single play episode if the toys were combined in any way (e.g., banging them together or using several objects in a pretend play sequence such as cooking). In cases where a play episode was interrupted by a look at the TV (when the TV was on), a play episode was coded as ending only if the look lasted longer than 3 s or, if the look was shorter than 3 s, the child did not return to the same toy.

The third pass recorded the onsets and offsets of focused attention during object play for each play episode. Coders were trained to recognize the behavioral characteristics associated with focused attention as described by Ruff and Rothbart (1996). These behaviors included a serious facial expression with furrowed brow, a forward leaning posture toward the object, and minimized extraneous body movements. A similar 3-s rule was employed in that brief looks away from the toy were not coded as ending focused attention provided that the child looked away for less than 3 s and returned to a state of focused attention with the same object.

A fourth pass coded maturity of play using the 12-point scale published by Belsky and Most (1981). This scale was supplemented by two additional levels adapted from an unpublished scale by McCune-Nicholich (1980) to encompass play by somewhat older children (36-month-olds) than had been observed by Belsky and Most. A numerical value was assigned to each level of play. Levels 1 through 12 were exactly as described by Belsky and Most, and Levels 13 and 14 were those added for the purpose of the current study. For instance, "mouthing" or "simple manipulation" (touching a toy), according to the scale by Belsky and Most, received a 1 or 2, respectively. An episode of "functional-relational" play, in which the child combined two objects in a meaningful way (e.g., touching a spoon to a plate), received a 5. A self-directed symbolic play episode received a 7, whereas a play episode involving "substitution" (e.g., the child put a block up to a doll's mouth as though it were a bottle while talking about feeding the doll) received a higher score of 9. Level 13 was used to indicate object agency with descriptive and functional language. Thus, this level designated times in which the child played the role of a doll within a pretend play scheme (e.g., the child attributed dialogue to a plastic Fisher-Price doll). Last, object play in which the child incorporated imaginary objects for which there was no concrete referent received a code of 14.

Play maturity was coded continuously from the beginning to the end of each previously identified play episode. If the maturity of play changed within a play episode, as it often did, coding encompassed that change.

A videotape of a typical child at each age was used for training. A research assistant worked with the training tape until he or she achieved acceptable reliability with an experienced coder (phi correlation greater than .70). At this point, the assistant was asked to code a test tape. The assistant was allowed to code tapes from the study only if he or she attained a high correlation with the supervisor's test tape coding for both the onsets and the offsets of the target behavior.

To assess interobserver reliability (IOR), two independent observers scored 4 participants at each age (12 in all) for each measure. These IOR tapes were distributed throughout the entire coding period to monitor reliability over the course of the study. Agreement was acceptably high for all behaviors. Intraclass correlations were .85 for mean play length, .69 for mean length of focused attention, and .98 for mean level of play maturity weighted by the time spent at each level. Although 12 tapes were double-coded for looks and deemed acceptably high, due to experimenter error, there is only a record of 4 of those double-coded tapes. The phi correlations (a measure of temporal overlap calculated for each pair of observers) for these tapes were all above .90.

Results

The initial analyses for the play measures were 3 (age: 12, 24, and 36 months) × 2 (sex: male and female) × 2 (test order: TV first and TV second) × 2 (condition: TV and no TV) analyses of variance (ANOVAs) with condition as a repeated measure. Dependent measures were percent of session spent in play, mean play episode length, percent of play that was focused, mean length of focused play, and average maturity of play weighted by time spent at each level. An additional between-subjects ANOVA (excluding the condition variable) was run to analyze the total number of looks at the television when it was on.

The ANOVAs revealed order effects for play episodes, focused attention, and the total number of looks at the television. Investigation of these effects indicated that there were systematic curvilinear changes in these measures over time. Therefore, hierarchical linear modeling (HLM) was used to systematically analyze change over time and to isolate the effects of TV and other factors. HLM is a particularly powerful statistical tool for investigating measures that are differentially expressed over time and can simultaneously assess continuous within- and between-subjects factors without overestimating power (for more details on this method, see Raudenbush & Bryk, 2002). Outcome variables for the HLM analyses were measured in 6-min intervals to account for changes over time. For play episodes and focused attention, one set of HLM analyses assessed the effect of TV condition. A second set of analyses assessed the particular influence of looks at the TV screen on play measures during the TV condition. These tests are described in detail within each section below. Because no order effects were found for play maturity, only the simpler results from ANOVA are presented here.

Bivariate correlations between all dependent variables are presented in Table 1. Descriptive statistics for all the dependent measures are presented in Table 2, but the reader should note that these are unadjusted means and as such do not control for variability with time or other factors accounted for in the HLM analyses. A brief description of how to interpret the HLM results can be found in the Appendix. All reported results are significant at alpha level $p < .05$ or better.

Number of Looks at Television

The HLM analysis for number of looks at the TV included linear and quadratic change over time (measured in 6-min intervals) as Level 1 (within-subjects)

Table 1
Bivariate Correlations Between Dependent Variables

	Play percent	Play length	Focused percent	Focused length	Play maturity
Play percent	1.00	.62**	.29*	.47**	.47**
Play length	.62**	1.00	.37**	.63**	.63**
Focused percent	.29*	.37**	1.00	.71**	.38**
Focused length	.47**	.63**	.71**	1.00	.56**
Play maturity	.47**	.63**	.38**	.56**	1.00

$*p < .05$. $**p < .01$.

predictors and child age, sex, and order of conditions as Level 2 (between-subjects) predictors. Looks at the TV were quite short, and visual attention averaged about 5% indicating that television was truly in the background for these children (see Table 2). HLM analyses revealed that the overall number of looks at the TV was greater when the TV condition was presented in the second half hour, producing a significant effect of order, $B = -48.09$ ($SE = 9.65$), $t(47) = -4.98$. The number of looks at the TV generally decreased over time that the TV was on, particularly from the first 6-min interval to the second as indicated by a significant positive quadratic slope, $B = -12.27$ ($SE = 2.59$), $t(48) = -4.73$, $p < .001$, and $B = 0.70$ ($SE = 0.15$), $t(49) = 4.57$, $p < .001$, for linear and quadratic slopes, respectively. The increase in looks at the screen when TV was presented in the second half hour was largely due to more looks in the first 6-min interval that the TV was on, as indicated by a significant effect of order on the time slope, $B = 7.86$ ($SE = 1.69$), $t(48) = 4.66$. Furthermore, looks diminished with age, primarily because 3-year-olds had fewer looks at the TV than the two younger groups (see Table 2; Figure 1), $B = -1.05$ ($SE = 0.28$), $t(47) = -3.73$. Sex was not a significant predictor of the number of looks. The decline in look number from the first 6-min interval to the second suggests that children habituated attention to the TV somewhat during the first 6 min but that there was no further habituation.

Table 2

Means (SEs) for All Dependent Measures as a Function of Age and Condition

	Looking at television			Play episodes		Focused attention		Maturity
	Percent	Number	Length	Percent	Length	Percent	Length	Weighted average
12 months								
TV	5.51 (1.32)	26.55 (2.98)	3.09 (0.31)	65.70 (5.02)	42.57 (7.73)	21.08 (3.84)	12.72 (1.73)	2.65 (0.13)
No TV	—	—	—	71.11 (4.46)	50.65 (6.85)	29.85 (4.97)	17.58 (1.88)	2.60 (0.09)
24 months								
TV	6.15 (1.12)	26.13 (3.06)	3.83 (0.43)	70.82 (3.53)	73.69 (14.14)	36.80 (4.50)	22.29 (2.14)	4.86 (0.35)
No TV	—	—	—	75.37 (3.58)	74.51 (9.79)	31.77 (5.17)	20.60 (3.03)	4.86 (0.41)
36 months								
TV	3.06 (0.68)	16.55 (2.98)	2.93 (0.36)	75.80 (3.35)	72.72 (7.04)	43.59 (5.29)	31.80 (5.00)	5.02 (0.34)
No TV	—	—	—	79.76 (3.13)	106.68 (13.61)	44.81 (5.81)	33.78 (4.32)	5.52 (0.32)
Average								
TV	4.88 (0.64)	23.08 (1.74)	3.27 (0.21)	70.77 (2.37)	62.78 (6.00)	33.44 (2.92)	22.27 (2.19)	4.16 (0.23)
No TV	—	—	—	75.42 (2.19)	77.33 (6.79)	35.55 (3.17)	24.06 (2.10)	4.31 (0.25)

Note. Dependent measures are looking at television (percent of TV condition spent looking at screen, number of looks at TV, and length of looks), play episodes (percent of session spent in play and length of episodes), focused attention (percent of play that was focused and length of focused attention episodes), and play maturity (average maturity of play weighted by time spent at each level). All lengths are measured in seconds. For maturity of play, numbers denote qualitative level of play.

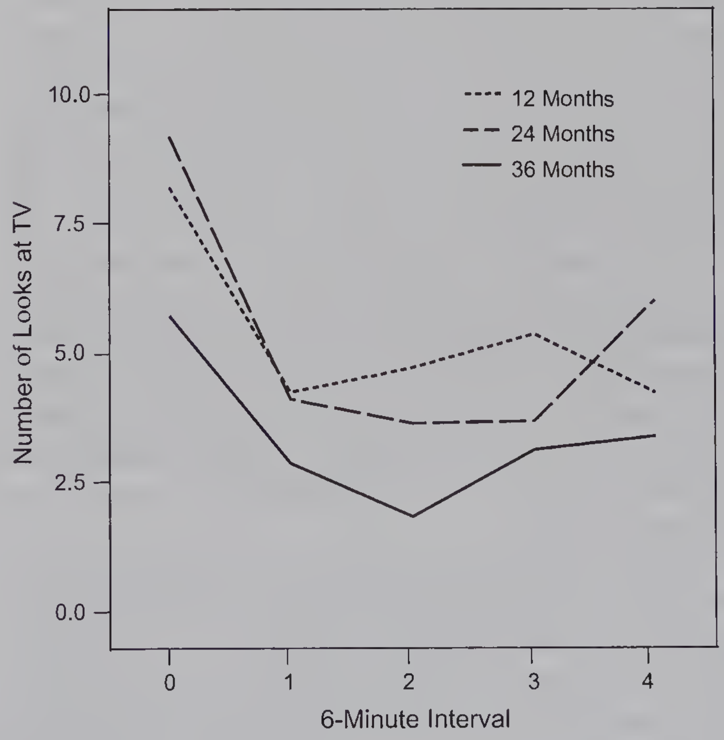

Figure 1. Mean number of looks at TV per 6-min interval as a function of age (values are unadjusted by hierarchical linear modeling coefficients).

Importantly, analyses of the effects of TV on play that excluded data from the first 6-min interval did not affect conclusions resulting from analyses of all the data. That is, the initial novelty of the TV program did not by itself account for any of the results described below. Another important consideration is that because play episodes and episodes of focused attention were coded so that they ended if the child looked at the TV longer than 3 s, it is possible that effects of TV in reducing play or focused attention length are due to these longer looks at the TV (about 30% of all looks). Consequently, we performed analyses considering only looks at the TV that were less than 3 s in length as well as only those longer than 3 s. There were no substantial differences in results from those reported below; that is, looks at the TV that lasted less than 3 s had about the same effects per look on the dependent variables as looks longer than 3 s.

Play and Focused Attention as a Function of Condition

The first set of HLM analyses on play episodes and focused attention considered the dependent measures as a function of condition (TV and no TV). For these analyses, Level 1 (within-subjects) HLM predictors included condition, linear change over time (6-min intervals), quadratic change over time, and interactions between these factors. Level 2 (between-subjects) predictors included age and sex of the child, order of conditions (TV first and TV second), parent education (i.e., highest level achieved), familiarity with the toys in the playroom (i.e., how many of the toys were similar to ones the child had at home), exposure to TV at home (i.e., average of parent-reported hours for each day of the week), and how frequently the child looked at the television in the lab (i.e., total number of looks at the screen as an individual difference measure). All the above factors were assessed as predictors of the outcome measures, but only those that significantly improved the overall model were included in the final models. Specifically, to minimize the chance of Type I error due to multiple tests, only those predictors that significantly contributed to the total amount of variability explained by the model, based on HLM hypothesis testing, are presented here.

Percent of interval spent in play. The percent of each interval spent engaged in toy play decreased over time spent in the room, $B = -0.84$ ($SE = 0.33$), $t(49) = -2.58$. Condition was also a significant Level 1 predictor in the final model for percent of time spent in toy play, $B = -5.08$ ($SE = 1.86$), $t(49) = -2.73$. In this model, condition explained an additional 4.06% of within-subjects (Level 1) variability not accounted for by the model without TV (i.e., after controlling for time). Children played less by about 5 percentage points, or 18 s per 6-min interval, when the TV was on. Because play decreased by about the same amount as the children looked at the TV (i.e., 5% of the session), it seems likely that looking at the TV simply displaced ongoing play.

Length of play episodes. A small decrease in the total amount of play in an interval does not necessarily mean that the length of play episodes decreased. Consequently, play episode length was analyzed separately as a function of condition. The final model for mean play episode length included linear and quadratic change as significant Level 1 predictors, $B = 27.61$ ($SE = 6.95$), $t(46) = 3.97$, and $B = -2.76$ ($SE = 0.76$), $t(46) = -3.64$, for linear and quadratic slopes, respectively. Furthermore, at Level 2, the size of the linear and quadratic slopes was predicted by an interactive combination of age and sex, $B = -23.57$ ($SE = 8.66$), $t(46) = -2.72$, and $B = 3.33$ ($SE = 1.03$), $t(46) = 3.22$, for the Age × Sex interaction on linear and quadratic coefficients, respectively. The overall change over time was such that the average length of play episodes increased until just after the midpoint of the 60-min session and then decreased. The Age × Sex effects were due to 3-year-old girls showing the most dramatic changes over time, whereas younger children and boys showed relatively less change over time. Adjusted for these effects, background television decreased play episode lengths such that play episodes were approximately 30 s shorter on average in the TV condition, $B = -30.16$ ($SE = 7.39$), $t(49) = -4.08$. Condition explained an additional 4.30% of within-subjects variability not accounted for by the model without TV. The only residual variance remaining to be explained by the final model was for the effect of TV suggesting that other factors, such as individual differences not captured by age, sex, toy familiarity, home TV exposure, and parent education, may play a role in the effect of background TV. In sum, play episode lengths changed over time in an inverted-U fashion, particularly for older girls, and became substantially shorter in the presence of background television when controlling for these general changes over time.

Percent of play that was focused. Because background TV reduced the total amount of play, we analyzed the percent of play that was accompanied by focused attention. The final model for percent of focused play included only linear change as a predictor at Level 1. Significant Level 2 predictors in the final model included the effect of age on the intercept and an Age × Sex interaction on the slope for time. The amount of play that was focused increased by about 11% per year of age, B = 10.98 (SE = 3.99), t(48) = 2.75. In addition, the percent of play that was focused decreased linearly over time, B = −0.82 (SE = 0.38), t(46) = −2.16. This was particularly true of males and younger females, B = −1.59 (SE = 0.63), t(46) = −2.52. The effect of TV condition and the quadratic slope was not significant for the percent of play that was focused, although significant variability remained to be explained suggesting that changes occurred in different directions for individual children. No Level 2 variables in the current study were able to sufficiently predict these changes.

Length of focused episodes. Even though the percent of focused play changed little in the presence of TV, the lengths of episodes of focused attention were affected. The final model for all data for mean length of focused episodes included linear and quadratic change over time and condition at Level 1. Similar to the results for mean play episode length, in this model, the quadratic slope was negative such that initially length of focused attention episodes increased until just after the midpoint and then decreased, B = −0.40 (SE = 0.19), t(48) = −2.13. Furthermore, age was a significant Level 2 predictor of the quadratic slope insofar as the changes over time were more dramatic for older children, B = −0.65 (SE = 0.17), t(48) = −3.87. Adjusted for these effects, television decreased the mean length of focused attention episodes by approximately 5 s (almost 25%) during the first interval, B = −5.06 (SE = 2.17), t(49) = −2.33. Condition accounted for an additional 5.73% of within-subjects variability. There was significant variability remaining to be explained for change over time and the effect of TV. Again, these are likely due to unexplained individual differences.

Play and Focused Attention in the Presence of TV as a Function of Looks at the Screen

The second set of HLM analyses was conducted using only the data from the TV sessions for each subject. Rather than assessing play behavior as a function of condition, in this second set of analyses, the number of looks at the TV screen was included as a Level 1 predictor to determine the extent to which this measure of distraction by the TV predicted variation in outcome measures when the TV was on. In other words, for each participant, the outcome measure within a 6-min interval (e.g., percent of that interval spent in play) was assessed as a function of the number of looks at the TV that occurred during that same 6-min interval. Other within-subjects predictors were linear and quadratic change over time and interactions between time and looks at TV. Between-subjects factors at Level 2 included order of conditions, parent education, toy familiarity, and home TV exposure.

Percent of interval spent in play. When considering data from the TV condition alone, the amount of time spent in play decreased significantly over time, B = −2.21 (SE = 0.97), t(49) = −2.28. In addition, the percent of the interval spent in play significantly decreased by an average 2.3% with each additional look at the TV screen in an interval (see Figure 2), B = −2.31 (SE = 0.38), t(49) = −6.15. Children spent more time engaged in toy play during intervals in which they had relatively few looks at the TV screen as compared to intervals during which they had more looks at the screen. The number of looks at the screen accounted for 14.27% of within-subjects variability remaining to be explained after controlling for change over time. Similar to findings reported above, the negative effect of look number on play behavior held even when excluding data from the first 6 min of the session during which looks at the TV were particularly high as well as when considering only those looks that were less than 3 s in length.

Length of play episodes. The number of looks per 6-min interval was also a significant negative predictor of the length of play episodes in the TV condition (see Figure 3), B = −3.32 (SE = 0.94), t(49) = −3.54. For each additional look at the TV in an interval, the mean length of play episodes in that interval dropped by an

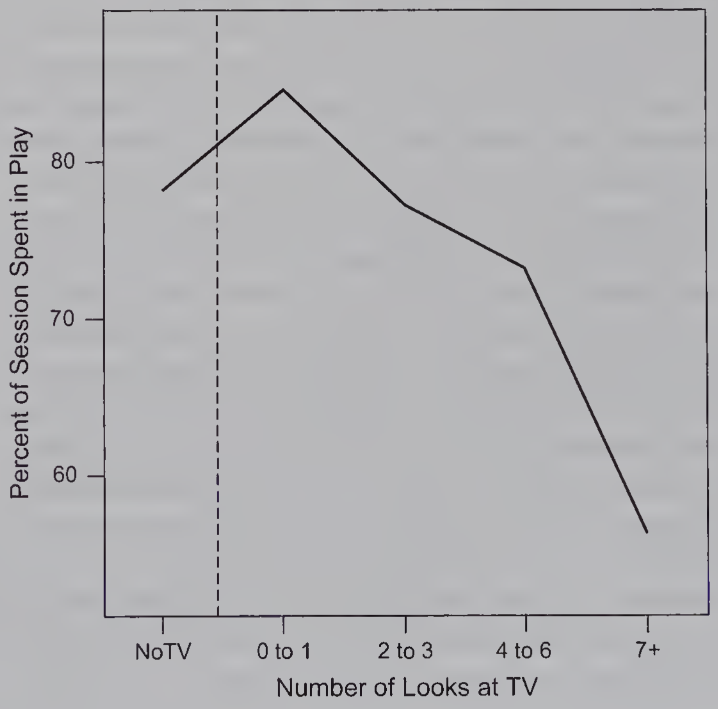

Figure 2. Mean percent of 6-min intervals spent in play as a function of the number of looks at the TV.
Note. Values are unadjusted by hierarchical linear modeling coefficients. Average percent of session spent in play for the no TV condition is provided for reference.

Note. Average episode length during the no TV condition is provided for reference.

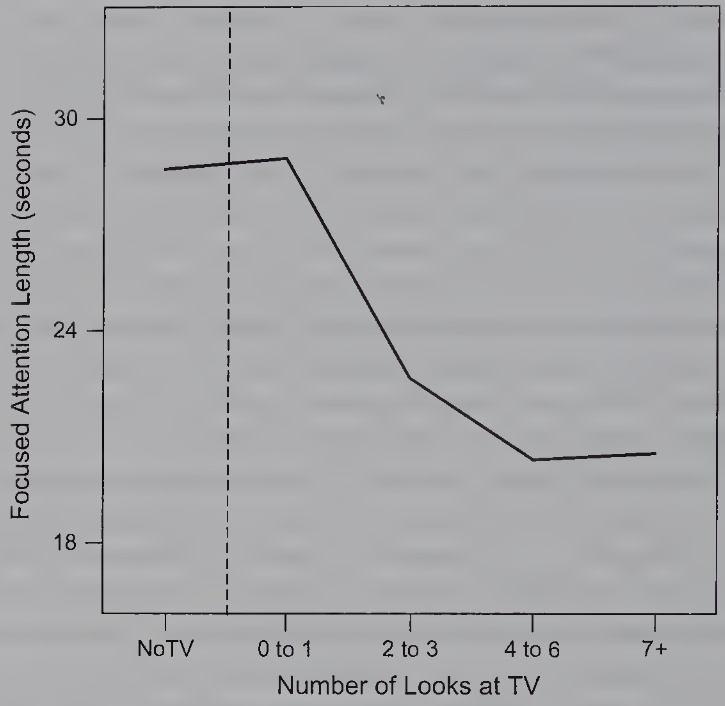

Figure 4. Mean length of focused attention episodes per 6-min interval during the TV condition as a function of the number of looks at TV during that interval.

Note. Average episode length during the no TV condition is provided for reference. Means are unadjusted by hierarchical linear modeling coefficients.

average of 3.3 s. The number of looks at the screen per interval accounted for an additional 4.57% of within-subjects variability.

Percent of play that was focused. As with the HLM analysis on the entire session, the percent of play in the TV condition that was focused increased with age, $B = 10.88$ ($SE = 3.07$), $t(48) = 3.55$. Although the percent of play that was focused in the TV condition did decrease somewhat as a function of the number of looks at the screen, this effect was not significant.

Length of focused play episodes. The quadratic slope was significant reflecting the same inverted-U changes over time that were found in the first analysis on length of focused episodes, $B = -13.41$ ($SE = 3.56$), $t(48) = -3.77$, and $B = 3.20$ ($SE = 0.79$), $t(48) = 4.06$, for linear and quadratic slopes, respectively. Furthermore, the number of looks at the TV was a significant predictor of the length of focused attention as shown in Figure 4, $B = -1.14$ ($SE = 0.45$), $t(48) = -2.53$. The length of focused attention episodes decreased by an average 1.14 s per look at the TV. The number of looks at the screen accounted for 19.91% of within-subjects variability remaining to be explained.

Maturity of Toy Play

Weighted average play maturity. Because exploratory analyses of maturity of toy play indicated that there were no order effects indicative of systematic changes over time, the results presented are from mixed ANOVAs. For average play maturity (weighted by the time spent at each level of maturity), the analysis was a 3 (age) × 2 (sex) × 2 (order of conditions) × 2 (condition) ANOVA with condition as a repeated measure. The only significant main effect for average maturity level was age, $F(2, 38) = 42.87$. Post hoc analyses revealed that the 12-month-olds (mean level = 2.62) differed significantly from the two older age groups but that the 24- and 36-month-olds were not significantly different from each other (mean levels = 4.86 and 5.28, respectively). There was also a significant interaction between age and order of conditions, $F(2, 38) = 4.90$. Average maturity of play by 36-month-olds was greater when the TV condition was presented first than when it was second. There were no significant main effects or interactions with respect to the presence or absence of background television.

Time spent at each level of play. Exploration of the play maturity data indicated that the children spent the vast majority of their play at only 4 of the 14 levels: Level 2 (simple manipulation), Level 3 (functional), Level 5 (functional-relational), and Level 10 (sequence pretend). Level 3 refers to appropriate play with an object according to its standard intended use. An example is turning the crank on a jack-in-the-box.

Level 5 refers to play that puts two or more objects together in an appropriate manner (e.g., putting lids on pans). Level 10 refers to play that involves pretend acts in a related series (e.g., picking up doll, getting bottle, feeding doll with bottle, putting doll in bed). Together, these four categories accounted for 84, 82, and 83% of total play for 12-, 24-, and 36-month-olds, respectively. An ANOVA was conducted to determine whether TV had a differential effect on any of these four levels of play maturity. Time spent at each of these four levels was subjected to a 3 (age) × 2 (sex) × 2 (order) × 2 (condition) × 4 (level of play: 2, 3, 5, and 10) ANOVA with condition and level as repeated measures.

The omnibus ANOVA revealed a significant Condition × Level interaction that was explored by ANOVA on each level independently. Because of the large number of subordinate tests run, a more stringent significance level of .01 was adopted. There was a significant main effect of age for Levels 2, 5, and 10, $F(2, 38) = 40.89$, $F(2, 38) = 16.79$, and $F(2, 38) = 14.44$, respectively. Post hoc analyses (*t* tests with Bonferroni correction) revealed that 12-month-olds engaged in significantly more play at Level 2 (51% of play vs. 24% and 18%) and significantly less play at Levels 5 (8% vs. 22 and 31%) and 10 (0.5% vs. 14 and 16%) than 24- and 36-month-olds. The two older age groups did not differ significantly at any level.

The only level of play maturity demonstrating a significant effect of TV was Level 3 (functional play). For functional play, there was a significant Condition × Order interaction such that there was more play at this level in the second session compared to the first, particularly when TV was presented second, $F(1, 38) = 16.80$. In the first half hour, Level 3 accounted for 17% of play for children with TV and 16% for children without TV. In the second half hour, children with TV spent 31% of play at Level 3, whereas children without TV spent 24% of play at Level 3. A compensatory decrease in Level 5 play in the presence of TV approached significance, $F(1, 38) = 5.19$.

Discussion

We found that very young children's toy play was disrupted by background television. Specifically, compared to no television, there was less play overall, shorter play episodes, and shorter bouts of focused attention in the presence of background television. Given these findings, it was surprising that there was little overall reduction in focused attention and that maturity of play was affected in a limited way. Although there was some reduction in functional-relational play in the presence of television with a compensatory increase in functional play, there was no reduction in complex, high-level play as predicted. Overall, the disruptive effects are real but small.

We hypothesized that background television would disrupt play by repeatedly eliciting an OR toward the television screen and away from ongoing play activities. The hypothesis was supported insofar as children frequently oriented toward the TV screen for short periods of time, although there was a reduction of such looks after the first 6 min of the program. The more frequently the child looked at the TV screen, the greater was the disruption of play.

The overall reduction of play in the presence of background television is likely due to displacement by looking at the screen. The cumulative time spent playing was reduced by about 5% in the half hour that the television was on, just about the same as the 5% of time spent looking at the television. Although an important finding on its own, this reduction in overall time spent playing is not sufficient to account for the reduced length of play episodes. The overall reduction in play also does not account for the reduction in lengths of focused attention or the slight reduction in play maturity. It is likely that in very young children, brief looks at background television disrupt ongoing play schemes. When the child stops looking at the TV, he or she may have forgotten the ongoing play scheme or otherwise find it difficult to reinstantiate the scheme in which case a new scheme is initiated with another toy. In fact, in the presence of television, children were more likely to move from toy to toy, coming into contact with an average of 65% of the toys as compared to 55% when the television was not on.

Background television has been shown to reduce adults' performance on a variety of complex cognitive tasks. This has been interpreted as the television competing with the primary task for cognitive resources (e.g., Armstrong & Greenberg, 1990). Assuming that toy play is cognitively demanding in very young children, interference with play could be expected as well. Background television may also be implicated in a more general kind of interference associated with noisy environments. Children exposed to excessive noise (e.g., from airports or motor traffic) do less well on tests and on tasks requiring concentration (Hygge et al., 2002). With respect to very young children, the level of ambient noise in the home is negatively related to cognitive development (Gottfried, 1984; Wachs, 1985, 1986; Wachs & Gandour, 1983). In a related vein, Landry, Smith, Swank, and Miller-Loncar (2000) found that the extent to which parent interactions disrupt children's ongoing play negatively predicts children's subsequent cognitive and language skills. These authors proposed that interrupting children's play requires them to repeatedly refocus attention and may tax children's limited cognitive resources. Background television may have an analogous effect.

This research raises the question of the influence of background television in children's natural environments. Assuming that the effects found in this experiment occur at home, it is as yet unknown whether chronic reductions in play episode lengths and focused attention lengths produced by background television are parts of a causal chain leading to negative long-term consequences. Nevertheless, short play episode lengths are a marker for poor developmental outcome (e.g., Faden & Graubard, 2000; Handen et al., 1998; Malone, 1997) as is reduced focused attention during play (Lawson & Ruff, 2004). Moreover, children's sustained attention has been shown to mediate effects of family environment (composite of physical environment and caregiver responsiveness) on school readiness (National Institute of Child Health and Human Development Early Child Care Research Network, 2003).

Although the present research shows that background television plays a proximate causal role in reducing play episode length and focused attention, it remains for future research to determine whether this suite of effects is by itself causal in poorer developmental outcomes. Prior research on background noise in the home, of which background television is a considerable component, has identified a negative relationship between such noise and mothers' verbal responsiveness to the child (Corapci & Wachs, 2002). This suggests that background television may exert an influence beyond its direct effects on very young children's solitary toy play as observed in the present work. Indeed, in a subsequent experiment following a design parallel to the present study, we found that the quality and quantity of parent–child interactions are also affected as parents watch or become distracted by television (Kirkorian, Murphy, Pempek, Anderson, & Schmidt, 2005). It is also possible that chronic exposure to television that is constantly left on in the home is correlated with other factors, such as a generally chaotic home environment (Wachs, 1986). Taken together, however, reduced parent–child interactions, combined with reduced focused attention during play and reduced play episode length, lead us to hypothesize that background television, as a chronic influence, is by itself an environmental risk factor in children's development.

It is possible, of course, that background television does not induce effects that are necessarily negative but instead induces a characteristic style of attention deployment, a style that may be appropriate in some situations but not in others. Correa-Chavez, Rogoff, and Arauz (2005), for example, argue that the attentional style of traditional village-reared Latin American children differs from that of European American children with parents who have received extensive schooling. These distinctions (attending sequentially vs. simultaneously to multiple information sources) are produced by substantially different childhood experiences and may prove optimal in different situations (e.g., learning in school vs. observationally learning from village activities). From this point of view, background TV may induce an attentional style that is not necessarily negative in all situations. For example, it is possible that it can provide some basis for later multitasking skills. Contemporary American youth are characterized as simultaneously talking on cell phones and playing computer games even as they monitor TV (Foehr, 2006). It has not yet been shown whether such media multitasking is associated with generally positive or negative outcomes.

Our basic conception of background television is that it functions as a continuously varying distractor for very young children. Whereas it is thought that distractibility decreases with age, and the evidence supports this in school-aged children (e.g., Strutt, Anderson, & Well, 1975), Ruff and Rothbart (1996) note that there is little evidence for a developmental trend in distractibility for children aged 5 years and younger. In the present study, if looking away from toy play to the television is taken as a measure of distraction, the 3-year-olds looked fewer times than younger children. Consistent with Ruff and Rothbart's model of attention development, play length and focused attention also increased with age. However, we did not find an age difference in the disruptive effects of background television, a continuously changing audiovisual distractor. Rather, all ages had reduced play episode and focused attention lengths.

It is possible that these effects are uniquely produced by television as a distractor. Ruff and Capozzoli (2003) examined the effects of an intermittent audiovisual distractor on the toy play of 10-, 26-, and 42-month-olds. Like the present study, they found a decrease in distractibility over time; their experimental session was 12 min in length. However, they found no difference in distractibility as a function of age as evidenced by looks at the distractor. Ruff and Capozzoli (2003), moreover, found that the intermittent distractor did not reduce either length or amount of focused attention during play. It could be that the difference between studies is due to the continuously changing nature of background television, but the differences might also be due to several factors including the longer observation period, a greater number of toys in the present experiment, general age differences, or other procedural differences.

In conclusion, even though the effects of background television on play behavior found in this study are small, they may have a cumulative impact through large amounts of exposure at home. These may include poorer cognitive and language development and attention deficit symptoms as found in associations from a small number of studies that focus on very young children (Carew, 1980; Christakis et al., 2004; Nelson, 1973; Wachs, 1985, 1986; Zimmerman & Christakis, 2005). Researchers to date, lacking direct evidence, have tended to attribute these associations to negative effects of television programs made for young children and to which they are highly attentive (e.g., Christakis et al., 2004). The present research, in contrast, is suggestive that programs made for adults and watched by parents may in fact provide a risk factor for development and could conceivably account for the negative associations with cognitive and language development. This study demonstrates that it is imperative for future research on the influence of media in the home to distinguish between the possibly greatly differing effects of foreground and background television exposure.

Appendix

	Coefficient (*SE*)	Significance test
Constant		
Intercept	57.32 (10.76)	*t*(47) = 5.36, *p* < .001
Age	−1.05 (0.28)	*t*(47) = −3.73, *p* = .001
Order	−48.09 (9.65)	*t*(47) = −4.98, *p* < .001
Time		
Intercept	−12.27 (2.59)	*t*(48) = −4.73, *p* < .001
Order	7.86 (1.69)	*t*(48) = 4.66, *p* < .001
Time squared		
Intercept	0.70 (0.15)	*t*(49) = 4.57, *p* < .001

The table in this Appendix presents the HLM final model for the number of looks at the screen in the TV condition. Order is a dichotomous variable such that a value of 1 represents the TV first order, whereas a value of 0 represents the TV second order. Centering, or transforming variables such that a value of 0 represents a point (actual or estimated) in a data set, is a common practice in HLM analyses. This allows the constant (i.e., the value of the outcome measure when all other variables are set to 0) to be a meaningful value. In this case, age is represented in years and centered at its mean such that a value of 0 represents age 2 years, 1 year of age is represented by a value of −1, and 3 years of age is represented by a value of 1. Time is centered at the first interval of the TV condition such that a value of 0 represents the average for the first 6 min that the TV was on, a value of 1 represents the second 6-min interval, and so on.

Coefficients for "intercept" are the intercepts of the Level 2 equations; coefficients for all other factors are the slopes associated with those predictors. Level 1 (within-subjects) variables can be interpreted in much the same way as in regression analyses. Level 2 (between-subjects) predictors can be interpreted as regression coefficients for the Level 1 slopes. The constant represents the value of the outcome measures when all predictors are set to 0 (the intercept in a standard regression equation). For example, based on the above model, the average number of looks at the screen in the first interval of the TV condition (Time 0) for 2-year-olds (age 0) when TV was presented in the second half hour (Order 0) was about 57. When TV was presented in the first half hour (i.e., when order has a value of 1), the constant is reduced by about 48, resulting in an average of only 9 looks in the first interval for 2-year-olds. The negative slope for age on the constant indicates that the average number of looks decreased with age (approximately one look per 6-min interval per year of age).

There was also a significant negative linear component, indicating that the number of looks generally decreased over the course of the TV condition. Order is a positive predictor of that slope. When TV is presented in the second half hour (i.e., when order is 0), the linear slope is about −12.3; when TV is presented first (i.e., when order has a value of 1), the linear slope increases by a factor of about 7.9, making it only −4.4 for this order. Thus, the number of looks generally decreased with time that the TV was on but less so when TV was presented first than when it was presented second. Last, the positive slope for time squared suggests a U-shaped function with respect to time; this is manifest in a large decrease in looks from the first interval to the second and relatively little change over time thereafter.

German Children's Comprehension of Word Order and Case Marking in Causative Sentences

Miriam Dittmar
Max Planck Institute for Evolutionary Anthropology and University of Zurich

Kirsten Abbot-Smith
University of Plymouth

Elena Lieven and Michael Tomasello
Max Planck Institute for Evolutionary Anthropology

Two comprehension experiments were conducted to investigate whether German children are able to use the grammatical cues of word order and word endings (case markers) to identify agents and patients in a causative sentence and whether they weigh these two cues differently across development. Two-year-olds correctly understood only sentences with both cues supporting each other—the prototypical form. Five-year-olds were able to use word order by itself but not case markers. Only 7-year-olds behaved like adults by relying on case markers over word order when the two cues conflicted. These findings suggest that prototypical instances of linguistic constructions with redundant grammatical marking play a special role in early acquisition, and only later do children isolate and weigh individual grammatical cues appropriately.

One of the important tasks of early childhood is mastering a conventional language. Languages differ not only in their words but also in the grammatical constructions they employ for assembling words into meaningful utterances. Grammatical constructions are composed of multiple words, or word categories, structured into patterns in particular ways by such things as word order and grammatical markers (e.g., a different ending on a word when it is the subject rather than the direct object in a sentence—so-called case marking). In English, the sentence "The dax mibbed the gazzer a toma" (the ditransitive construction) implies a transfer of some kind, even though all the contentful words are meaningless (Goldberg, 1995).

One construction of particular importance in early development is the basic transitive construction, prototypically used to indicate an agent causally acting on an object, as in simply "The dax mibbed the gazzer." The importance of this construction stems from the fact that it is one of the ontogenetically earliest in which it is critical to distinguish the different roles of the participants in some event. Thus, "The toma mibbed" creates no problems for deciding who was doing the action because there is only 1 participant. But if we hear "The toma the gazzer mibbed," we must decide who is mibbing whom, and to do this we need to understand the grammatical conventions of the particular language being learned. Interestingly, in most languages, there are multiple, redundant cues for helping the listener do this in many utterances—although in other utterances, there can be just a single cue. For example, in the English sentence "He mibs pencils," we identify the agent of the action as *he* based on the facts that: (a) it is said before rather than after the action word or verb (word order), (b) it is the subject pronoun *he* (and not the object pronoun *him*; case marking), (c) it agrees in number with the verb (we say "He mibs" but "Pencils mib," without an -s; subject–verb agreement), and (d) it is a statistical fact that animate beings, such as male persons, are more likely to act on inanimate things, such as pencils, than the other way around (animacy). A child acquiring the English transitive construction, therefore, could on a particular occasion be using any or all these cues to determine who is mibbing whom in the utterance.

Many thanks to Elena Rossi, Lena Verfürth, Eva Leermann, Jan Jurkat, and Julia Ulber for assistance in testing and for organizing appointments; to Silke Brandt, Susanne Grassmann, and Catherine van Maanen for coding reliabilities; to Petra Jahn for technical assistance; and to Daniel Stahl for help with counterbalancing and statistics. A special thank you to the parents and children who participated in the study.

The competition model of Bates and MacWhinney (1987, 1989) represents an attempt to assess how children acquire the different cues of different languages—especially in the transitive construction—and how they weigh these cues relative to one another when they conflict (see also Slobin & Bever, 1982). In a comprehension task in which they were asked to identify who was doing what to whom, young children heard a sentence such as "Him kissed she." Case-marked pronouns indicate that the female kissed the male (she > him), but word order indicates that the male kissed the female (him > she). The finding is that from early in the preschool period English-speaking children privilege word order over all other tested cues (e.g., animacy and subject–verb agreement) in interpreting transitive sentences. Other researchers have tested English-speaking children's comprehension of word order when it is the only cue available (therefore not conflicting with any other cues) and found that even young 2-year-olds already distinguish between such things as "X is tickling Y" and "Y is tickling X" (Hirsh-Pasek & Golinkoff, 1996, with familiar verbs; Gertner, Fisher, & Eisengart, 2006, with novel verbs).

In many other languages, the grammatical cues in transitive sentences are much more evenly weighted than in word-order dominant English. For example, various languages in which all nouns are case marked for their role in the sentence (not just pronouns, as in English), have a much more flexible word order—because if a word is locally marked with a case marker indicating its role in the sentence, then word order may be used for pragmatic functions such as emphasis and perspective (as English does awkwardly in such sentences as "**Him** I like"). Therefore, if German adults are presented with a sentence parallel to the English sentence above ("Him kissed she"), they interpret it in the opposite way to English adults, that is, they insist that the subject-marked pronoun *she* indicates the one doing the kissing even though it comes after the verb (whereas it most often comes before the verb) (MacWhinney, Bates, & Kliegl, 1984).

Importantly, in the competition model, there are methods for quantifying the strength of various cues in a particular language, for example, in the transitive construction. To do this one looks at the general dimensions of the frequency of a cue (cue availability), the consistency of a cue in indicating a function (cue reliability), and the complexity of a cue (cue cost). In English, case-marked pronouns (e.g., *I–me, he–him*) are highly reliable in transitive sentences (when they are present they indicate accurately agent and patient), but they are not always available (often there are only full nouns, which are not case marked). Word order is almost always available in German, but it is often not reliable (because sometimes transitive sentences have the agent after the verb and the patient before it—which works because they are both case marked for role). These two dimensions of cues—availability and reliability—can be combined to give an overall measure of cue validity (Kempe & MacWhinney, 1998).

With respect to acquisition, Bates and MacWhinney (1987) predicted that children should acquire first those cues with highest cue validity. In addition, because sometimes several cues may indicate the same function—providing extra information—children should find it especially easy to comprehend prototypical transitive sentences with both word order and case marking (and perhaps other cues) working in coalition: the coalitions-as-prototypes model (Bates & MacWhinney, 1987). This should be true especially if, as is often the case, the prototype occurs very frequently. An agent of a transitive action, for instance, should be identified most easily by a German child if it is not only marked by its position before the verb but also by the relevant case marker. In a study of English- and Italian-speaking children, Bates et al. (1984) provided evidence for this approach by comparing the use of word order and animacy cues (agents tend to be animate, patients inanimate) in transitive sentences. They found that the high cue validity of word order in English led English 2-year-olds to rely on word order and ignore animacy when these two cues conflicted (i.e., when they heard "The pencil is kicking the cow" they tried to make the pencil kick), whereas the low cue validity of word order in Italian led Italian 2-year-olds to rely on animacy and ignore word order (making the cow kick the pencil).

Some researchers have proposed that the particular aspects of cue validity that children follow change over development. In a study with Hebrew-speaking children and adults, Sokolov (1988) found that cue availability—how often a cue occurs—played a stronger role in sentence interpretation for younger children, whereas cue reliability—the proportion of relevant sentences for which a particular cue correctly indicated agent or patient—played a stronger role for older children and adults. Of special importance, children have to notice which cue adults follow when two cues conflict (conflict validity). In many cases, this may be a quite drawn-out process, as the relevant conflict situations are sometimes fairly rare in the language children experience (McDonald, 1986). Supporting this general view, Matessa and Anderson (2000) found that in adult artificial language learning cue validity predicted which cues are used early in the learning process and conflict validity predicted which cues are used in later learning.

Cue cost (essentially, complexity) has been much less studied. Building on Slobin's (1982) local cues hypothesis, one claim is that "local cues" such as case marking can be processed on the spot without taking the entire sentence into account, whereas "distributed cues" such as word order impose a greater burden on short-term processing capacity (because sentential fragments need to be held in memory until the next relevant component is processed). Support for this hypothesis was provided by Lindner (2003), who found that early in development German children tended to rely on "local cues" and only later on "distributed cues," although Lindner's analyses did not involve a direct comparison between conditions in which the different cues supported or conflicted with one another. Studies that have made such a direct comparison have found that German preschool children comprehend sentences in which case marking and word order conflict, more poorly than sentences in which case marking and word order collaborate (e.g., Mills, 1977; Primus & Lindner, 1994; Schaner-Wolles, 1989). However, these studies differ as to the age at which German children accurately comprehend sentences with conflicting cues, probably because the different studies used only sentences with highly familiar verbs, and exactly which verbs were used varied between studies. The use of familiar verbs makes it possible that children could respond on the basis of only verb-specific knowledge (e.g., knowing only that the hitter comes before *hit*), whereas mature grammatical knowledge is based on verb-general, abstract knowledge of grammatical constructions.

In the current study, we investigated German children's understanding of word order and case marking cues in transitive sentences, and—unlike previous studies in the competition model framework—we did this using novel verbs. Our specific question was when German children come to understand that in their language case marking is a 100% reliable cue (even if it is not always available), whereas word order is not (even though it is quite often available). In our two experimental studies, we gave children test sentences that contained various combinations of word order and case marking cues—all grammatically correct, with animacy neutralized across agent and patient. In one condition, the two cues supported one another: Case marking and word order both indicated the first noun as the agent. In a second condition, these two cues were in conflict: Word order indicated the first noun as the agent, whereas case marking indicated the second noun as agent. Finally, in a third condition, agent and patient were case-marked ambiguously and therefore the only cue children could rely on was word order. Following Bates and MacWhinney's (1987) concept of coalitions-as-prototypes, we predicted that sentences containing multiple, redundant cues (as in the first condition) should be easiest to acquire. From McDonald's (1986) findings, we predicted that sentences containing conflicting cues (as in the second condition) should be the most difficult because robust knowledge of relative cue reliabilities—from relatively rare conflict situations—is needed for adult-like comprehension. The findings from this study should be relevant not only for elucidating basic processes of language development but also for elucidating processes of children's learning more generally because it addresses such domain-general issues as the role of prototypes, the individuation of particular cues from prototypes, and children's sensitivity to more local versus more distributed cues in sequential learning.

Study 1

As a preliminary study to our two comprehension experiments, we first looked at how German adults use word order and case marking in transitive sentences addressed to young children. Because the competition model predicts that the cue validity of word order and case marking should play a key role in children's comprehension—and that cue availability and reliability might play different roles at different points in development—we computed all values for these two cues from a corpus of child-directed speech.

The German grammar relevant to the current studies is as follows. In active transitive sentences, the agent of the action is subject and is marked with nominative case marking, and the patient is direct object and is marked with accusative case marking. For both of these, the case marking is either a special form of pronoun or a noun with a special form of determiner (e.g., *a* or *the*). For example, if a dog is agent, the form is *der Hund* (the + nominative dog) or *er* (he), whereas if a dog is patient, the form is *den Hund* (the + accusative dog) or *ihn* (him). Additional complexity comes from the fact that nominative and accusative marking take different forms when applied to nouns of different genders, and in some cases, they are not distinct. For example, unlike the example of *dog* above (which is masculine), if a cat is the agent, the form is *die Katze* (the + nominative cat), but if a cat is the patient, the form is exactly the same *die Katze* (the + accusative cat). This means that in some instances, case marking is not an available cue in the sense that it does not identify case role unambiguously. Finally, although in German transitive sentences agents typically come before the verb and patients after the verb, as in English, to highlight the patient pragmatically the reverse order may be used—with the case roles marked by case marking and unaffected by the reverse order. "Den **Hund** beisst der Mann" has the first noun, *Hund*, marked as accusative, and the second noun, *Mann*, marked as nominative and so, despite word order, the man is biting the dog.

Method

For our analysis, we used Child Language Data Exchange System (CHILDES) data of spontaneous speech by German mothers to six monolingual normally developing children (Szagun, 2004). At the time of the first recording, the children were 1.8 years old, and at the time of second recording, they were 2.5 years old. We analyzed the sample of 7,032 utterances previously examined by Stoll, Abbot-Smith, and Lieven (in press), which these authors had coded into syntactic construction types. We examined the following categories where transitives might occur—transitives, complex sentences, subject-predicate-other, and verb fragments—and extracted transitive verbs by hand. Sentences with transitive verbs were excluded when they involved idioms, such as *Hunger haben* "to be hungry" (literally: have hunger) and passive constructions were also excluded. First, we divided all transitive sentences into sentences with verbs that were highly causative with a volitional agent and affected patient, such as *schubsen* "to push," and those with verbs that did not have any causative meaning, such as *sehen* "to see" (Hopper & Thompson, 1980). Then, we analyzed whether the sentence was complete, that is, with two noun phrases or whether it was a fragment, that is, subject or object was dropped.

We coded all transitive sentences for case marking in terms of whether they were unambiguous (i.e., it was clear which noun phrase was agent and which was patient) or ambiguous and for word order (subject-first or object-first). In addition, we coded which kind of case marker (i.e., which lexical form) was used. We followed Kempe and MacWhinney's (1998) formula for calculating cue availability, cue reliability, and cue validity for the case marking and word order cues that assign agent and patient. Availability of a cue was therefore defined as the number of sentences in which a cue is present, divided by the total number of transitive sentences. Reliability of a cue was defined as the ratio of sentences in which a cue correctly indicated the agent, divided by the number of sentences in which the cue was present. Finally, cue validity was defined as the product of availability and reliability. For our main analyses, we included only transitive sentences with highly causative verbs because only they contain both agent and patient. Nevertheless, we also compared these with our data for the noncausative transitive sentences and report the differences. All coding was carried out by the first author, and an additional coder coded 15% of all sentences for reliabilities. There was a high level of agreement between coders (Cohen's Kappa = 0.92).

Results and Discussion

Of our final sample of 745 transitive sentences, 410 (55%) contained highly causative verbs, and 335 (45%) were without causative meaning. Of the 410 transitive sentences with highly causative verbs, unambiguous case marking was found in 351 transitive sentences (86%) and 59 sentences (14%) contained ambiguous case marking. Fifty-five (13%) of the highly causative transitive sentences were fragments; that is, they involved either subject or object ellipsis. Of all complete highly causative sentences (with two noun phrases), 280 (79%) had a subject-first word order and 75 (21%) had an object-first word order.

To summarize, we found that in most (68%) of the complete causative transitive sentences (fragments excluded) both case marking and word order referred to the first noun as the agent. In 21% of the sentences, case marking and word order conflicted with each other because the second noun of the sentence was marked with nominative and/or the first one with accusative. In 11% of the sentences, word order was the only cue that referred to the first noun as the agent because the sentence contained ambiguous case marking. Only two sentences (less than 1%) appeared with an object-first order and ambiguous case marking.

When transitive sentences with noncausative verbs were included, similar results were found apart from the fact that object-first order appeared a bit more often (33%) and subject-first order with unambiguous case a bit less (56%). The proportion of sentences with subject-first order and ambiguous case marking was identical (11%). Of special relevance to the experiments of Study 2, we should note that marking case in German by definite determiners is not the most common way of marking (especially) agents of transitive sentences (with causative verbs) because quite often pronouns, which are always case marked, are used. The use of definite determiners to mark agents or patients was quite rare for agents (16%) but frequent for patients (60%). Within the transitive sentences with causative verbs, 8% of the agents were marked with *der* (the + masculine + nominative), 7.5% were marked by *die* (the + feminine), and finally only 0.5% were marked with *das* (the + neuter). Patients were mostly marked with *das* (30% of all transitive sentences), followed by *die* with 17%, and the rarest was *den* (the + masculine + accusative) at 13%.

Because we were interested in the relative strength of word order and case marking as cues for identifying agents, we calculated cue availability, cue reliability, and cue validity for both following Kempe and MacWhinney (1998). But whereas it is relatively easy to determine whether the case marking cue is available or not (unambiguous nominative and accusative forms), it is difficult to know exactly how German children use the word order cue. There are two possible ways. First, the position of one argument in relation to the verb might be sufficient to decide whether this noun phrase is agent or patient (subject-verb vs. verb-object). That is, *die Frau schubst* (the + feminine woman pushes) is likely to mean "the woman is pushing," whereas *schubst die Frau* (pushes the + feminine woman) is likely to mean "is pushing the woman." Under this analysis, the word order cue would also be available in fragment sentences (with either the subject or object omitted). Then, we find that the word order cue is available 100% of the time and the case-marking cue in 89% of the transitive sentences. In terms of reliability, however, case marking in German, when available, always reliably indicates the agent and patient of a transitive sentence 100% of the time, whereas we find that word order does this reliably only 74% of the time (because objects can come before, and subjects after, the verb). Therefore, the cue validity for case marking is higher with 89% compared to 74% cue validity for word order.

However, there is a second possible way to calculate the availability of word order because in German the position of the verb in the sentence is relatively flexible. It can either be at the beginning of a sentence as in questions, in the middle as in main clauses, or at end in subordinate clauses. Therefore, in a sentence such as, "..., *weil der Mann den Jungen schubst*" (..., because the + masculine + nominative man the + masculine + accusative boy pushes) the object (patient) comes directly before the verb, although the word order still maintains the most common (canonical) subject before object order. Thus, in fragment sentences without case marking, it is very difficult to say whether a noun phrase immediately before the verb is the agent or the patient ("*hat die Frau geschubst*" could either mean "he has pushed the woman" or "the women pushed him"). If we therefore decide that the word order cue is not available in German fragment sentences, that is, those with subject or object omission because the child needs to hear the relation between two arguments in the sentence to use the word order cue, we find even stronger differences. In this case, the availability of word order drops (87%) to almost the same as that of case marking (86%) and, once validity is calculated (with 100% reliability for case marking and 79% reliability for word order), case marking is even more valid with 86% cue validity in contrast to only 68% cue validity for word order (see Figure 1). This may be the more accurate calculation because German children hear transitives with subject or object omission 13% of the time. However, we will compare our data from the following experiments with both calculations using the different definitions of word order cues.

Study 2

We use the findings from Study 1 to make various predictions about which kinds of transitive sentences German children should comprehend most readily and at the earliest ages. If what is most important from the beginning is cue reliability—as suggested by MacWhinney et al. (1984)—or cue cost—as suggested by the local cues hypothesis (Slobin, 1982)—then children should comprehend most readily sentences with unambiguous case marking regardless of the order in which the noun phrases occur (i.e., even in object-first sentences). On the other hand, if what is most important from the beginning is cue availability—based mainly on frequency in the input—then they should comprehend most readily sentences in

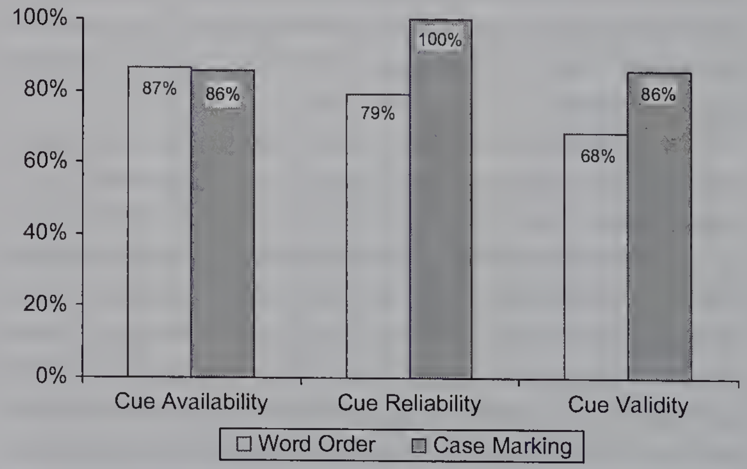

Figure 1. Availability, reliability, and validity of the grammatical cues word order and case marking for German transitive sentences in child-directed speech (Study 1).

which the agent is the first noun phrase, regardless of case marking (i.e., even in sentences with ambiguous case marking). Finally, if prototype sentences with redundant marking have a special role—as suggested by the coalitions-as-prototypes approach of Bates and MacWhinney (1987)—then children should comprehend most readily prototype sentences and might be expected to struggle when the cues conflict (i.e., in object-first sentences). Of course, it is also possible as we pointed out in the introduction and as suggested by Sokolov (1988) that cue availability, cue reliability, and prototypes play different roles at different periods of development.

In Study 2, we test these predictions experimentally using an act-out comprehension task, which is the task used most often in previous investigations of the competition model and local cues hypothesis. We adapted this task to examine how young German children perform when they hear sentences containing **novel** verbs to determine when and in which developmental order they start to use these grammatical cues productively, independent of any particular known verbs and independently of animacy cues.

Method

Participants

Sixteen monolingual German 2.7-year-old children (range = 2.6–2.8; 9 girls and 7 boys) and 16 monolingual German 4.10-year-old children (range = 4.6–5.3; 9 girls and 7 boys) were included in the study. An additional 9 children were tested but excluded from the study due to either fussiness (3), bilingualism (1), experimenter error (4), or because the child was too young (1). Children were recruited from a database of parents who volunteered to participate in psychological studies. They came from diverse social economic backgrounds. All children were tested in nursery schools in a medium-sized German city.

Materials

All verbs referred to prototypical causative-transitive actions, involving direct contact between a volitional agent and an affected patient. All actions were reversible (Hopper & Thompson, 1980). The two novel verbs *wiefen* and *tammen* were used to describe two novel transitive actions that were performed with two novel apparatuses. *Wiefen* was used to refer to an animal rocking another animal standing on a rocking-chair-like apparatus by pulling it toward itself with its head. *Tammen* referred to an animal pushing down another animal standing on a platform with a spring underneath it by jumping on its back.

Agents and patients of a particular event were pairs of animals with the same grammatical gender. Exactly which gender depended on the condition. The animals were all well known to 2-year-olds. We used the Elternfragebogen (Grimm & Doil, 2001), a much-shortened German version of the MacArthur Communicative Development Inventory (Fenson et al., 1994) to identify which animals to use. *Der Hase* "the (+masculine) bunny," *der Bär* "the (+masculine) bear," *der Elefant* "the (+masculine) elephant," *der Hund* "the (+masculine) dog," *die Katze* "the (+feminine) cat," and *das Schwein* "the (+neuter) pig" were on the Elternfragebogen. *Der Löwe* "the (+masculine) lion," *der Frosch* "the (+masculine) frog," and *der Tiger* "the (+masculine) tiger" were on the U.S. American MacArthur. Just two animals (*das Zebra* "the [+neuter] zebra" and *die Ziege* "the [+feminine] goat") were on neither of them, but the children did not show any difficulty in identifying these animals (see the Procedure section).

All children heard the same test sentences (see Appendix A) in three conditions: In the prototype condition, they heard the novel verbs with an argument structure in which the agent was the first noun phrase and case marked with nominative, and the patient was the second noun phrase and case marked with accusative, for example, *Der Hund wieft den Löwen.* "The (+nominative) dog is weefing the (+accusative) lion." In the "word-order-only" condition, they heard an argument structure in which the agent was the first noun phrase and the patient was the second noun phrase, but case marking was ambiguous because animals of masculine gender were not used, for example, *Die Katze wieft die Ziege.* "The cat is weefing the goat." In the conflict condition, the patient was the first noun phrase and case marked with accusative and the agent was the second phrase and case marked with nominative, for example, *Den Bären wieft der Tiger.* "The (+accusative) bear is weefing the (+nominative) tiger" (with the meaning: it is the tiger that is weefing the bear). As a control condition, we used one familiar verb *schubsen* "to push" in the prototype argument structure, for example, *Der Hund schubst den Tiger.* "The (+nominative) dog is pushing the (+accusative) tiger." Therefore, each child heard seven test sentences, six with novel verbs and one with a familiar verb.

Design

We tested each child with the two different novel verbs and the familiar verb in transitive sentence structures using an act-out task. A camera in front of the children recorded their enactment. Counterbalancing was used for the agent (e.g., lion/dog) and for sides, for example, sometimes the agent was to the left and sometimes to the right of the patient. The order of the verbs and the conditions was counterbalanced by Latin squares. There were 72 possible orderings of which 16 were chosen randomly, and these were distributed evenly over the children within each age group.

Procedure

During the session, the child sat at a small children's table on which the apparatuses for the act-out task were placed. The experimenter sat next to the child. Animals and apparatuses for the act-out task were hidden in a box. The two animals for each act-out task were always placed by the experimenter in front of the child between the child and the apparatus facing the child so that it was never the case that one animal was nearer to the apparatus. We counterbalanced which animal (agent or patient) was to the left of the child both within and between subjects.

Warm-up. The children first experienced a warm-up in which they were required to imitate acting out an intransitive locative (namely: *Der Fisch springt über den Elefanten.* "The [+nominative] fish is jumping over the [+accusative] elephant"). If they did not correctly act this out, they got a second trial with the sentence *Der Fisch klettert auf den Elefanten.* "The (+nominative) fish is climbing onto the (+accusative) elephant." If the child passed one warm-up trial correctly we proceeded with the experiment.

Word learning training. Prior to all three-test conditions each child was taught the name of the novel verb in the following manner. Using animals which take German feminine gender that does not decline for nominative or accusative case (e.g., *Kuh* "cow" and *Ente* "duck"), every verb (novel and familiar) was presented to each child in a live act out by the experimenter in a variety of argument structures: in the citation form with no arguments (e.g., *Das heißt wiefen.* "That's called weefing") as well as in transitive argument structure with two feminine pronouns (which are identical for subject and object position in German) in three different tenses (*Sie wird sie wiefen.* "She is going to weef her"; *Sie wieft sie.* "She is weefing her"; *Sie hat sie gewieft.* "She weefed her"). The child was also asked to repeat the verb in the citation form (e.g., *Kannst du das sagen: wiefen?* "Can you say this: weefing?") and to attempt the act out with the two feminine animals.

Test trial. For the act-out trials, the experimenter placed two animals in front of the child and told the child the test sentence: *Jetzt bist du dran! Zeig mir: Der Löwe wieft den Hund.* "Now it's your turn! Show me: The (+nominative) lion is weefing the (+accusative) dog." The experimenter repeated the test sentence until the child started enacting.

Vocabulary/morphology production posttest. After all test trials were over, the children took part in a language development test. The 2.7-year-olds received the vocabulary production subtest of the SETK 2 that has been standardized for German 2- to 3-year-olds (Grimm, 2000). In this, the children are shown cards with pictures of objects that they have to name. The 4.10-year-olds received the morphological production subtest of the SETK 3–5, which has been standardized for German 3- to 5-year-olds (Grimm, 2001). In this, children are shown pictures with familiar and novel objects and they had to build the correct plural form (of which there are eight possibilities in German). The 2.7-year-old children who participated in the test had a mean score of 44 (range = 36–56), and the 4.10-year-olds had a mean score of 47 (range = 36–63). The mean scores were, therefore, a bit lower than the expected ones for their age range (expected $M = 50$, $SD = 40-60$).

Coding and Reliability

For every test trial, the correct response was to choose the correct animal as agent of the action. If the child did not act out a causative scene but instead put both animals next to each other onto the apparatus we excluded those trials. We had to exclude 26 trials of 144 in the younger age group (prototypical condition [9], word-order-only condition [9], and conflict condition [8]) and none in the older age group. All children were coded by the first author, and an additional coder coded 15% of all trials for reliabilities with high agreement with the first author (Cohen's Kappa = 0.8774).

Results and Discussion

The data were analyzed using a 2 (age) × 4 (experimental condition) mixed factorial analysis of variance (ANOVA). There were main effects for both Condition, $F(3, 81) = 3.018$, $p < .05$, and Age, $F(1, 27) = 17.672$, $p < .001$, but not a significant Condition × Age interaction. Post hoc tests with a Bonferroni correction for the main effect of condition with six comparisons revealed only significant differences between the 4.10-year-old's performance with the familiar-verb control condition (M = 94%) and the conflict condition, $M = 56\%$, $t(15) = -4.392$, $p < .05$. Nonparametric tests (Wilcoxon) found the same result.

Because the chance level for our dependent variable was always 50%, we also investigated in which conditions and at which ages the children were above chance. The results show that the 2.7-year-olds were only above chance with the familiar verb, $t(15) = 2.236$, $p < .05$. In contrast, the 4.10-year-olds were above chance in the familiar-verb condition, $t(15) = 7.000$, $p < .001$, the prototypical, $t(15) = 3.576$, $p < .05$, and the word-order-only condition, $t(15) = 3.478$, $p < .05$, see Figure 2. However, we did not find any correlation between the children's performance in this task and vocabulary/morphology scores and also no group differences when comparing high and low vocabulary/morphology children.

Thus, 2.7-year-old German children were only able to comprehend transitive sentences in this act-out task with a familiar verb. One possible reason for this is that children initially form grammatical schemas around familiar verbs and are therefore only able to comprehend transitives sentences correctly with familiar verbs (Tomasello, 2003). However, a second explanation of the results is that the act-out task is particularly difficult for young children and it might be easier to carry out when asked to perform a known action than a novel action. By contrast, the German 4.10-year-olds correctly interpreted transitive sentences with novel verbs in subject-first word order, presumably because they have productive knowledge of the grammatical cue word order. But in the conflict condition, they performed at chance level. This indicates that German 4.10-year-olds have not yet acquired the use of the case-marking cue separately from subject-first word order and therefore do not interpret correctly object-first sentences.

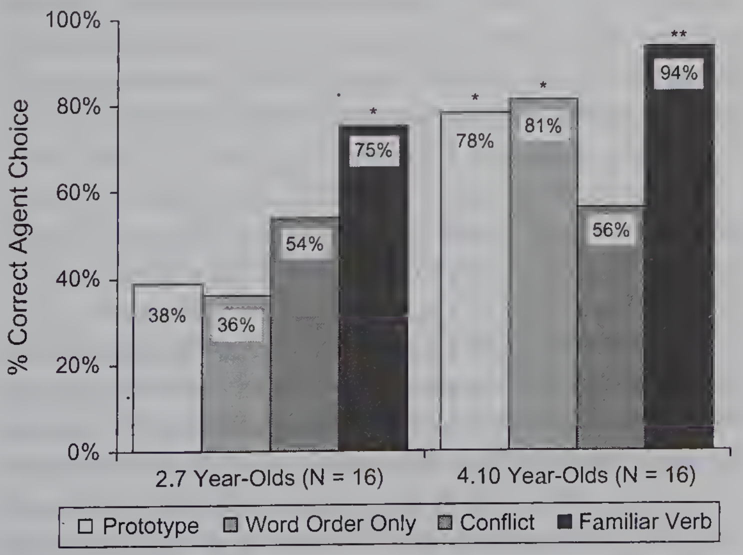

Figure 2. Mean proportion of correct agent and patient choices in the act-out task of Study 2, as a function of age and sentence type.

Study 3

It might be argued that the reason we found such late acquisition of case marking and verb-specific behavior in Study 2 is that the act-out task we used has high working memory and executive function demands. Some support for such an argument might be drawn from a previous study by Dittmar, Abbot-Smith, Lieven, and Tomasello (2008), who—contrary to the findings of the current experiment—found that German-speaking 2.6-year-olds did show productivity with novel verbs in transitive sentences in a pointing comprehension task. Therefore, in the next experiment, we adapted the pointing task to examine relative reliance on word order and case marking, using the same three novel verb conditions we used in Study 2. Furthermore, we tested a third age group of older children to try to identify a later point in language development when German children are able to comprehend object-first transitive sentences.

Method

Participants

The children were monolingual speakers of German, who were brought by a caregiver to a child lab in a medium-sized German city. Of these sixteen 2.7-year-old children (range = 2.6–2.8; 8 girls and 8 boys), sixteen 4.10-year-old children (range = 4.6–5.2; 8 girls and 8 boys), and sixteen 7.3-year-old children (range = 7.0–7.11; 8 girls and 8 boys) were included in the study. An additional 13 children were tested but excluded from the study due to either showing a side bias during the test trials (2), fussiness (7), bilingualism (2), or experimenter error (2). Children were recruited from a database of parents who volunteered to participate in psychological studies. They came from diverse social economic backgrounds.

Materials

All novel verbs referred to prototypical causative-transitive actions, involving direct contact between a volitional agent and an affected patient. Actions were reversible and involved either a caused change-of-state or change-of-location (Hopper & Thompson, 1980). The three novel verbs *wiefen*, *tammen,* and *baffen* were used to describe three novel transitive actions that were performed with three novel apparatuses. *Wiefen* was identical with the action used in Study 2 except that we emphasized the causality of this new event by making the agent force the patient into a handstand with the third repetition of the action. *Tammen* was also identical with the action used in Study 2 but we emphasized the causality of this new event by making the agent force the patient to fall sideways with the third repetition of the action. The third novel verb, *baffen,* referred to an animal spinning around another animal standing on a disk, and, with the third repetition of the action, the location of the patient was changed from being next to the agent to being further away.

Agents and patients of a presented event were the same pairs of animals as in Study 2 plus three more: *das Schaf* "the (+neuter) sheep" and *das Pferd* "the (+neuter) horse," which were on Elternfragebogen and *der Affe* "the (+masculine) monkey" which was on the U.S. American MacArthur-Bates Communicative Development Inventory (Fenson et al., 1994). The structural pattern of the test sentences (see Appendix B) was the same as described in Study 2. Each of the three conditions was tested with each of the three novel verbs, so that the children got nine test sentences. Unlike in Study 2, we did not test familiar verbs.

Design

We tested each child with three different novel verbs in transitive sentence structures using a pointing task. During the session, the children sat in front of a 31 × 49 cm "Apple Cinema Display" screen. The procedure of the pointing task was based on the Intermodal Preferential Looking (IPL) paradigm pioneered by Golinkoff, Hirsh-Pasek, Cauley, & Gordon (1987; see also Imai, Haryu, & Okada, 2005 for an adaptation of the IPL to a pointing task). For the test trials, the child saw two film scenes on the computer screen, each starting simultaneously and lasting 6 s. Both involved animals enacting the same causative event and differed only in that agent and patient roles were reversed. All children got alternating test sentences with the three different conditions and all three novel verbs were tested in one session.

For each test trial scene pair we counterbalanced which particular scene correctly matched the test sentence (e.g., for the pair "dog weef lion" and "lion weef dog" half of the children heard the German equivalent of "the dog is weefing the lion" and the other half heard the reverse). The order of the verbs and the conditions was counterbalanced by Latin squares. The target screen order was counterbalanced so that each side (left [L] or right [R]) was correct four or five times out of nine trials for each child (depended on counterbalancing order). The same side was never the correct choice more than twice in a row. No child experienced a condition in which the correct choice alternated regularly (e.g., LRLRLRLRL). For half of the children, the first correct side in the first trial was left and vice versa. There were 52 possible orderings for correct side of which 16 were chosen randomly and these were distributed evenly over the children within each age group. The direction of the action (from left to right or from right to left) was also counterbalanced.

Procedure

One camera from behind the children recorded their pointing behavior. Only children of the youngest age group sat on their parents' lap. When testing the older children, the parent sat behind the child on a separate chair. The parents whose children sat on their laps were asked to close their eyes during each test trial so as not to influence their child during pointing. We decided not to use headphones for the parents because we found that this distracted the children. The experimenter herself never looked at the screen during the test trials but always at the child.

Pointing practice training. To teach the children that the aim of the task was to point to one of two pictures on the computer screen, we used a very easy warm-up task with two pictures of objects, for example, "dog" and "duck," which appeared at the screen simultaneously. Then, the children were asked to point to one of the two objects (e.g., *Zeig mir das Bild: Das ist der Hund.* "Show me the picture: That's the dog"). The pictures were from the vocabulary comprehension subtest of the SETK-2 (Grimm, 2000). We repeated this task 10 times with different objects and all children solved it perfectly.

Word learning training. Similar to Study 2, every novel verb was presented to each child in a live act out by the experimenter in a variety of argument structures.

Film familiarization trials. Following the live enactment, for each verb the child then saw a familiarization trial in which he or she watched each of the two film scenes individually and heard the experimenter describing them in the citation form, for example, *Guck mal, das heißt wiefen.* "Look, that's called weefing," whereas the other half of the screen remained blank. The side where the children saw the first picture (left or right) was counterbalanced across and within subjects. At the end of each film scene, the experimenter pointed to each animal and asked the child "Wer ist das?" (Who's that?). The majority of the children had no problem spontaneously naming the participating animals. If a child did not name one of the animals, the experimenter told the child the name and asked him or her to repeat it, which almost all children then did.

Test trial. Following this a red dot focused the child's attention to the center of the computer screen. Then, the test trial began and the child watched the same two scenes as in the familiarization trials. But here they appeared simultaneously and were accompanied by a prerecorded linguistic stimulus with the target verb in transitive argument structure, for example, *Guck mal, der Löwe wieft den Hund.* (×2) "Look, the (+nominative) lion is weefing the (+accusative) dog." After the videos had stopped, the experimenter asked the child to point to the correct (still) picture by asking, for example, *Zeig mir das Bild: Der Löwe hat den Hund gewieft!* "Show me the picture: The (+nominative) lion weefed the (+accusative) dog!" If the child did not point the experimenter repeated the question a second time, but she never asked the child to point again once she/he had already done so.

Vocabulary/morphology production posttest. After all test trials were over, the children took part in a language development test. The 2.7-year-olds and the 4.10-year-olds received the same tests as in Study 2. The 7.3-year-olds received the morphological production subtest of the Heidelberger Sprachentwicklungstest in which children are shown pictures with familiar and novel objects and they had to form the correct plural or singular. This test has been standardized for 3- to 9-year-old Germans (Grimm & Schöler, 1998). The 2.7-year-old children achieved a mean score of 55 (range = 42–71), the 4.10-year-olds achieved a mean score of 56 (range = 38–69), and the 7.3-year-olds achieved a mean score of 49 (range = 40–59). The expected mean score is again 50 with a standard deviation between 40 and 60.

Coding and Reliability

For every test trial, the correct response was to choose the right animal as agent of the action. If the child did not choose either scene or pointed to both we excluded those trials. We had to exclude 19 trials of 144 in the youngest age group (prototypical condition [4], word-order-only condition [5], and conflict condition [10]), 1 (conflict condition) in the 4.10-year-olds, and none in the oldest age group. All children were coded by the first author, and an additional coder coded 15% of all trials for reliabilities with high agreement with the first author (Cohen's Kappa = 0.968).

Results and Discussion

The pointing behavior was analyzed using a 3 (age) × 3 (experimental condition) mixed factorial ANOVA. There were main effects for both condition, $F(2, 90) = 34.875, p < .001$, and age, $F(1, 45) = 19.258$, $p < .001$. However, these must be interpreted in the context of a significant Condition × Age interaction, $F(4, 90) = 5.855, p < .001$ (see Figure 3).

Post hoc tests with a Bonferroni correction for three comparisons revealed that the interaction was due to the 2.7-year-olds showing more correct pointing in the prototypical condition (M = 77%) than in the word-order-only condition, M = 50%, $t(15) = 2.595$, $p = .06$, and than in the conflict condition, M = 46%, $t(15) = 3.143$, $p < .05$. No difference was found between the word-order-only condition and the conflict condition. The 4.10-year-olds also pointed correctly more often in the prototypical condition (M = 88%) than in the conflict condition, M = 35%, $t(15) = 4.970$, $p < .001$, and also more often in the word-order-only condition (M = 94%) than in the conflict condition, $t(15) = 6.586$, $p < .001$. No difference was found between the prototypical condition and the word-order-only condition. The pattern of results for the 7.3-year-olds was generally the same as for the 4.10-year-olds—except that their performance in the conflict condition was much better (though still lower than the other conditions). That is, they pointed correctly more often in the prototypical condition (M = 98%) than in the conflict condition (M = 69%), $t(15) = 3.416$, $p < .05$, and more often in the word-order-only condition (M = 100%) than in the conflict condition, $t(15) = 3.758$, $p < .05$,—with no difference

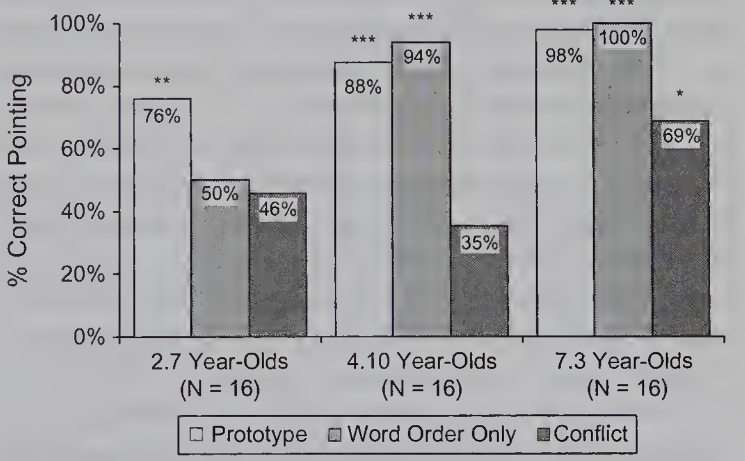

Figure 3. Mean proportion of pointing to the correct agent in Study 3, as a function of age and sentence type.

between the prototypical condition and the word-order-only condition.

Post hoc tests for the main effect of condition with Bonferroni correction revealed significant differences between all children's performance in the prototype condition ($M = 87\%$ correct pointing) and the conflict condition ($M = 50\%$ correct pointing, $t(47) = 6.601$, $p < .001$, and between the word-order-only condition ($M = 81\%$ correct pointing) and the conflict condition, $t(47) = 5.447$, $p < .001$. This indicates that conflicting cues, here word order and case marking, are especially difficult to use for children of all ages. Nonparametric tests (Wilcoxon) showed the same result.

Because the chance level for our dependent variable was always 50%, we also investigated in which conditions and at which ages the children were above chance. The results reflect the previous analyses, namely the 2.7-year-olds were only above chance in the prototypical condition, $t(15) = 4.354$, $p < .01$, whereas the 4.10-year-olds were above chance in both the prototypical, $t(15) = 9.121$, $p < .001$, and the word-order-only condition, $t(15) = 13.174$, $p < .001$, but not with the conflict condition. And finally the 7.3-year-olds reached ceiling in the prototypical and the word-order-only condition and were above chance in the conflict condition, $t(15) = 2.249$, $p < .05$. All analyses reflect a developmental trend whereby German children first acquire prototypical grammatical marking, followed by word order and only very late in age do they show an adult-like reliance on case marking when this conflicts with word order.

We were interested in what strategies young German children use to interpret transitive sentences with patients in first position. Therefore, we analyzed all children's responses to the conflicting sentences to see whether they oriented toward word order or case marking or whether they used neither strategy and avoided selecting a scene (usually through pointing to both scenes). A 3 (age) × 3 (strategy) mixed factorial ANOVA revealed main effects for both strategy, $F(2, 90) = 23.473$, $p < .001$, and age, $F(1, 45) = 21025.000$, $p < .001$. However, these must be interpreted in the context of a significant Strategy × Age interaction, $F(4, 90) = 6.362$, $p < .001$. Post hoc tests with a Bonferroni correction for three comparisons showed that 4.10-year-olds relied significantly more on word order than 7.3-year-olds, $t(30) = 2.622$, $p < .05$, and 7.3-year-olds relied more on case marking than 4.10-year-olds, $t(30) = -2.879$, $p < .05$, and 2.7-year-olds, $t(30) = -3.922$, $p < .001$ (see Figure 4).

Furthermore, we found that the performance of the 4.10-year-olds in the conflict condition was related to their state of morphological knowledge (plural morphology). Children who performed poorly on the morphological productivity posttest relied more strongly on word order in our experiment and therefore pointed incorrectly in the conflict condition ($M = 17\%$ correct pointing) than children with more robust morphological knowledge ($M = 54\%$ correct pointing), $t(14) = -2.460$, $p < .05$. The low-morphology group of children even showed below chance performance in the conflict condition, $t(7) = -5.372$, $p < .01$, which indicates a word order strategy. Similar findings come from the high-morphology group of 7.3-year-olds who showed above chance performance in the conflict condition, $t(7) = 3.122$, $p < .05$, whereas the low-morphology group of children still performed at chance. It may therefore be the case that German children pass through a stage in which they rely solely on word order and ignore case marking when these cues conflict before they learn to rely solely on case marking as adults do.

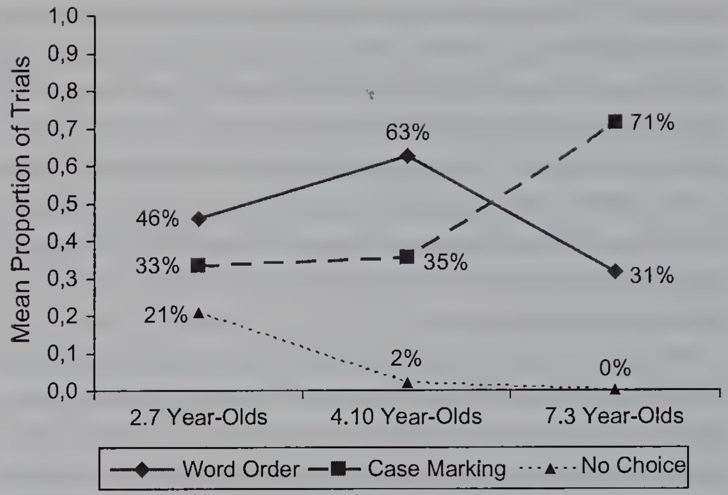

Figure 4. Strategies used (cue types relied on) during trials with conflicting cues in Study 3, as a function of age.

Our findings from Study 3 support the hypothesis that transitive sentences with a subject-first word order and with unambiguous case marking are acquired earlier by German children than are transitive sentences with a subject-first word order but ambiguous case marking. Furthermore, at age 5, German children have still problems correctly comprehending transitive sentences with object-first word order even when these are clearly case marked. By age 7, the majority of the children have solved this problem.

General Discussion

The current studies paint a fairly clear picture of how young German children come to comprehend causative transitive sentences. At around 2.6 years of age, if assessed with an act-out task (Study 2), they comprehend transitive sentences with familiar verbs but not novel verbs. This finding is in general agreement with the production study of Wittek and Tomasello (2005) in suggesting fairly verb-specific knowledge early in development. However, when a less demanding pointing task is used (Study 3), German children at this same age show solid comprehension of prototypical transitive sentences in which both word order and case marking indicate who was doing what to whom redundantly—even with novel verbs, suggesting more verb-general knowledge at 2.6 years. That they could show their knowledge only in the experiment using a pointing task and not in the act-out experiment might be due to the memory-burdensome nature of the act-out method per se with small children (Hirsh-Pasek & Golinkoff, 1996; Munakata, McClelland, Johnsons, & Siegler, 1997).

But, importantly, these children comprehended transitive sentences only in their prototypical form with redundant marking of agent and patient. Even with the less demanding pointing measure, they did not comprehend transitive sentences for which diagnostic case marking was absent or those in which the word order was noncanonical (object-first). They could not use either cue by itself, and they suffered when either was absent. These findings suggest that in languages like German children do not begin by attending to single cues, but rather they learn to comprehend the prototype and have difficulty whenever there is deviation from it. The prototypical form in German is also the most frequent (Study 1), presumably a common pattern crosslinguistically for case-marking languages. The role of subject–verb agreement in this process (and animacy as a semantic cue) should also be investigated.

The 4.10-year-old children present us with a puzzle. In both studies, using both methods, they seem to comprehend transitive sentences mostly in terms of word order. In both Studies 2 and 3, their performance with word order only is as high as with the full prototype including case marking (both near ceiling), and they choose at random in response to sentences in which word order and case-marking conflict—with a number of children in Study 3 actually ignoring case and going with word order only. This finding is a puzzle because on the two standard measures of input in the competition model—cue availability (how often the cue is available in relevant sentences) and cue reliability (how reliable the cue is, when it is present, in indicating the correct interpretation)—word order shows no advantage in availability (87% vs. 86% for case marking), and indeed its cue reliability as standardly computed is lower (79% vs. 100% for case marking).

One possible explanation of this finding is that the way we are thinking about grammatical cues is not fully adequate. It may be that cue availability and reliability as calculated here for word order miss aspects of the input that are important for language learning children. First, as noted above, it may be that German children do not use the word order cue as the positional relation between the two nouns in the sentence (first noun = agent; second noun = patient) but as the positional relation between the noun and the inflected verb (noun before verb = agent; noun after verb = patient). That would mean that the word order cue is also available in fragment sentences and hence more often available (100%) than case marking (89%). It is also possible that German children use the word order cue as the positional relation between the two nouns but do not take fragment sentences (with subject or object omission) as part of the transitive domain.

A second possibility, also alluded to above, is that German children do not use case marking in a completely general way. Because German has three noun classes, nominative case marking, for example, has three different forms in the singular and another in the plural. If children at a particular age have not yet discovered that all these forms mark the same case, then the way that cue reliability is typically calculated is not fully adequate. That is, the children in the current studies were tested on the particular case markers *der* and *den* used as determiners (masculine nominative and accusative), which appear in only 21% of all transitive sentences, and their comprehension of these may not benefit from their experience with case marking using pronouns, in which case the cue availability of these particular forms is not particularly high. But, of course, as children learn to connect the different case-equivalent forms (e.g., the nominative forms for nouns of different genders, as well as the nominative form for personal pronouns of the same gender), the cue availability of case marking will go up (even if the input stays exactly the same). Calculating the cue availability of case marking in this more item-based way results in the availability of case marking being much lower (21%) than that of word order (87%) even when assuming that word order is not available in fragment sentences.

Both approaches to calculating the cue availability of word order and case marking result in the conclusion that availability might indeed be higher for word order than for case marking. With this prediction, it would not be unexpected anymore for our 4.10-year-old children to rely more on word order than on case marking. This suggests that young German children rely on different input parameters at different stages of development; specifically, they rely more on cue availability (basically frequency) early in development and more on cue reliability later in development (see Sokolov, 1988, for similar findings). In agreement with this view, many studies have demonstrated the importance of frequency in early language development (see Lieven & Tomasello, 2008, for a review). Complicating matters further, many of the case markers in German are either not diagnostic within the transitive (*die* is both the nominative and accusative feminine; *das* is both the nominative and accusative neuter) or else ambiguous with forms outside the transitive (e.g., the masculine nominative form *der* is also the feminine dative and genitive). It is also important that in online sentence processing, German adults show faster reaction times when the test sentence only has a cue with high availability rather than one with high reliability (Kempe & MacWhinney, 1999)—even though in offline (less time-pressured) agent identification tasks they rely more on the cue with high reliability (see also the artificial language learning tasks of Matessa & Anderson, 2000). In all, it would seem that German word order is somehow a more straightforward cue for younger, less grammatically sophisticated children than is German case marking, which has so many different and ambiguous forms for the same grammatical function.

It must also be noted that the finding that German 4.10-year-olds rely more on word order than case marking does not accord well with Slobin's (1982) local cues hypothesis, which would predict the "local" case-marking cue to be easier to process than the "distributed" word order cue. However, German case marking differs in two ways from case marking in languages such as Turkish or Hungarian on which the local cues hypothesis was based (MacWhinney, Pleh, & Bates, 1985 for Hungarian; Slobin & Bever, 1982 for Turkish). First, whereas in Turkish and Hungarian case is marked by suffixes on the noun, in German case is marked on the determiner or adjective that precedes the noun. Therefore, one might suggest that case marking is not as local in German as in Turkish or Hungarian. Second, as just noted, the form of the German masculine nominative determiner *der* and accusative determiner *den* is ambiguous with determiner forms outside the domain of transitive sentences. Both factors, "less locality" and "ambiguity," may influence the ease of sentence or cue processing in German transitive sentences compared to Turkish or Hungarian.

Finally, we come to the 7.3-year-olds. We ourselves were very surprised that it was only at this late age that children succeeded in the conflict condition, weighing the case marking cue over the word order cue as adults do (Study 3). However, even adults have difficulties processing noncanonical word orders, at least as measured by reaction times (Ferreira, 2003; Kaiser & Trueswell, 2004). When German adults are confronted with object-first sentences that are ambiguously marked on the first noun phrase, they initially interpret these as subject-first sentences until they hear the second noun phrase (Weber, Grice, & Crocker, 2006). Moreover, in point of fact, our current findings do not differ greatly from those of other studies that have used familiar verbs. In the studies of Primus and Lindner (1994) and Schaner-Wolles (1989), it was not until children were 5 years of age that they correctly comprehended transitive sentences with familiar verbs with conflicting word order and case marking cues. Apparently, resolving conflicting cues in sentences with novel verbs takes even longer, though how much longer is not known as we did not test children between 5 and 7 years of age.

In terms of cue availability and reliability, following the reasoning from above, children by 7 years of age should know the grammatical equivalence of all (or at least most) of the different case forms serving the same grammatical function (and should ignore ambiguities based on other information). For 7-year-olds, then, the cue reliability of case marking is something close to that computed here; therefore, they finally rely on case marking over word order, as German adults would do. They also had much more experience than the younger children with sentences containing conflicting cues. One might argue that 21% object-first sentences in the input is plenty of exemplars for learning about conflicting cues by the age of 4.10; therefore, our children at this age should have been better. However, two other factors must be taken into account. First, object-first sentences occur in pragmatically marked contexts, with stress on the initial noun—which might mark them for children as a separate construction from prototypical transitive sentences without such stress. Second, almost all the object-first sentences in German child-directed speech have pronouns, not lexical nouns with determiners, in the pre- or postverbal position (96%), and most of these (76%) are first and second person personal pronouns with which the child is highly familiar. This means that the child can comprehend the vast majority of object-first transitive sentences on the basis of well-entrenched knowledge of specific pronoun forms and meaning but need not use case marking per se. Furthermore, the majority of the remaining 4% of the object-first sentences without pronouns provided an additional animacy cue to the child, that is, an animate agent versus an inanimate patient, despite the patient appearing in sentence-initial position. Overall, only 1% of all object-first sentences were based solely on the competition between the grammatical cues of case marking and word order. Therefore, in actual fact, young children hear very few conflict sentences in which they really are forced to decide between case marking and word order. This does not mean that the children in our experiments heard odd or ungrammatical sentences, just very infrequent ones if frequency is counted at the level of specific forms such as pronouns and particular case markers.

The overall process by which German children learn to comprehend transitive sentences in a verb-general way may therefore be summarized as follows. They begin somewhere after the second birthday by comprehending the prototypical form of such sentences (even with novel verbs) with redundant marking of agent and patient by means of word order and case marking. Between ages 2 and 4 they learn to use word order by itself, as well as a number of specific lexical forms like personal pronouns that appear in different case-marked versions. But it is only by sometime after age 5 that they become adult-like in weighing case marking over word order in sentences in which these cues conflict. Interestingly, this same process may help to explain why English-speaking children take so long to comprehend and produce sentences with novel verbs in experiments such as those summarized by Tomasello (2000). The prototypical transitive sentence in English potentially has animacy cues, a case marked subject pronoun (such as *I* or *he*), and subject–verb agreement—in addition to canonical subject-verb-object word order. In most of the experiments, all these cues were neutralized except word order. Following the reasoning of the current study, then, the prediction would be that English-speaking children should do better at an earlier age with prototypical transitive sentences including redundant cues. What this means is that all children learning all languages take time to learn the significance of individual cues when they experience those cues most often in combination with other redundant cues. This accords with the coalition model by Hirsh-Pasek and Golinkoff (1996) who suggested that children might master grammar by noting redundancies of cues for comprehension and with much recent theorizing in adult psycholinguistics in which the process of comprehension is seen as learning to integrate a great diversity of multiple probabilistic cues to language structure (the cue integration approach; see Christiansen & Monaghan, 2006).

In any case, the current study has demonstrated that even for what many researchers consider the most straightforward grammatical construction of all, the simple transitive, it can be a fairly long drawn-out process for young children to achieve adult-like mastery of the specific roles of each of the different grammatical cues instantiated in the particular sentences they hear. This mastery depends on their attention to basic aspects of their linguistic experience, such as the frequency, consistency, and complexity of those cues in particular utterances. Frequency, consistency, and complexity have also, of course, been centrally important in theories of children's nonlinguistic cognitive development and inductive learning (see Siegler, 1996). Our finding of the importance of the prototype and the long process of "unpacking" it into the different cues it contains, also finds resonance with much recent discussion of the relationship between prototypes and exemplar-based models in adult categorization learning (see, e.g., Anderson 1991; Chandler, 2002; Hampton, 1997; Ross & Makin, 1999). Although there is a great deal of theoretical and empirical work to be undertaken to make the links between these research fields more explicit, our results suggest to us that this aspect of children's language learning shows close parallels with essential characteristics of human learning more generally.

The Dynamics of Life Stressors and Depressive Symptoms in Early Adolescence: A Test of Six Theoretical Models

Margaret Clements and J. Lawrence Aber
New York University

Edward Seidman
William T. Grant Foundation

Structural equation modeling was used to compare 6 competing theoretically based psychosocial models of the longitudinal association between life stressors and depressive symptoms in a sample of early adolescents ($N = 907$; 40% Hispanic, 32% Black, and 19% White; mean age at Time 1 = 11.4 years). Only two models fit the data, both of which included paths modeling the effect of depressive symptoms on stressors recall: The mood-congruent cognitive bias model included only depressive symptoms to life stressors paths (DS → S), whereas the fully transactional model included paths representing both the DS → S and stressors to depressive symptoms (S → DS) effects. Social causation models and the stress generation model did not fit the data. Findings demonstrate the importance of accounting for mood-congruent cognitive bias in stressors – depressive symptoms investigations.

One theoretical approach to understanding the development of depression emphasizes the etiological role of stressful life circumstances. Early research in this area focused on major life stressors: acute and disruptive events that occur infrequently (Holmes & Rahe, 1967; Johnson, 1986). Later research incorporated minor stressors, events that occur more frequently, but are not as disruptive as major stressors (DeLongis, Folkman, & Lazarus, 1988; Kanner, Coyne, Schaefer, & Lazarus, 1981). School-related pressures or arguments are examples of minor stressors. Many cross-sectional and longitudinal studies have identified positive associations between both types of stressors and psychological symptoms, with most research inferring that experiencing multiple major and/or minor stressors leads to the development of psychological symptoms. However, there has been considerable debate regarding the validity of these conclusions.

One area of debate is whether and to what extent major and minor stressors actually lead to the development of depressive symptoms or whether a different causal process is in effect (Caspi, Elder, & Bem, 1987; Felner & Felner, 1989; Hammen, 1992b). The second debate focuses on the structure of the self-report measures typically employed in these studies. The concern here is that these measures include items that represent preexisting psychological adjustment, which results in inflated estimates of the association between life stressors and depressive symptoms (L. H. Cohen, Burt, & Bjorck, 1987; B. S. Dohrenwend, Dohrenwend, Dodson, & Shrout, 1984; Masten, Neeman, & Andenas, 1994). The current study contributes to the life stressors – depressive symptoms research by systematically comparing the fit of six competing theory-based psychosocial models, while at the same time addressing critiques regarding life stressors measurement.

Early Life Stressors Research: Three Social Causation Models

Most research investigating the association between stressful life circumstances and depressive symptoms applies a social causation theory of the stressors – depressive symptoms (S-DS) association, which suggests that stressors lead to symptoms. Early studies focused on major life stressors or "life events" (Coddington, 1972; Holmes & Rahe, 1967; Johnson, 1986). Although many cross-sectional and longitudinal studies found a positive relationship between major stressors and depressive symptoms in children and adolescents (e.g., Larson & Ham, 1993; Meyer et al., 1993; Towbes, Cohen, & Glyshaw, 1989), the effect sizes identified were typically small (Johnson, 1986; Rabkin

& Struening, 1976). In light of these small effect sizes, some researchers began to include other types of stressful circumstances. Lazarus and his colleagues emphasized the importance of the minor stressors that people encounter as part of daily life, emphasizing that these more proximal stressors may have a stronger association with maladaptive outcomes than major stressors (DeLongis et al., 1988; Kanner et al., 1981).

Previous research and theory have proposed three social causation models. Initial studies investigated an *independent effects* model, which suggests that both major and minor stressors have significant, independent effects on psychological adjustment (see Figure 1a). As Lazarus had anticipated, minor stressors explained more variance in psychological symptoms than did major stressors (Kanner et al., 1981), a finding that was replicated in cross-sectional studies of adolescents (DuBois, Felner, Meares, & Krier, 1994; Rowlison & Felner, 1988).

A second social causation model is a *mediated effects model*, which proposes that minor stressors result from the disruption caused by major stressors and mediate their impact (Rowlison & Felner, 1988; see Figure 1b. A study by Rowlison and Felner (1988) designed to test this theory found that minor stressors only partly mediate the association between major stressors and depressive symptoms and that both major and minor stressors have independent associations with psychological adjustment. In light of these findings, they suggested that a *partially mediated model* is more appropriate (see Figure 1c). However, findings have been inconsistent, with other adolescent researchers finding evidence of full mediation (Compas, Howell, Phares, Williams, & Ledoux, 1989; Wagner, Compas, & Howell, 1988). Further research is necessary to identify the process involved.

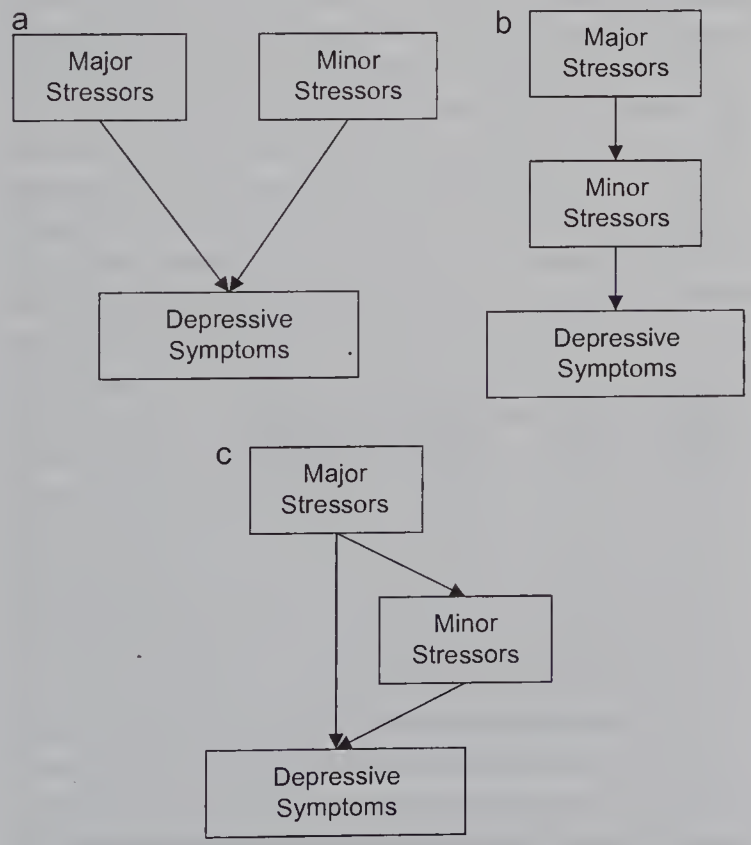

Figure 1. Heuristic models of social causation theories.

An important aspect of most S-DS studies is that they use a single wave of life stressors data to predict either a concurrent or a change in depressive symptoms. This research design continues to be used even though it has been subjected to two critiques. One critique focuses on the typical methods used to measure life stressors, and the second challenges the causal assumptions often made about the S-DS association. We review each of these issues below.

Life Stressors Measurement

One critique focuses on life stressors measurement techniques. Most studies use self-report checklist measures in which respondents check off the stressors they have experienced in a specified period of time. The concern is that these measures contain items that are confounded with the psychological adjustment measures they are predicting (L. H. Cohen et al., 1987; B. S. Dohrenwend & Dohrenwend, 1974; B. S. Dohrenwend et al., 1984). Specifically, life stressors measures often include items about negative experiences over which individuals have some control. To the extent that life stressors items reflect preexisting levels of psychological adjustment, they represent events that are *controllable* or *dependent* stressors, events, and circumstances that are at least partially dependent on the behavior of the individual (L. H. Cohen et al., 1987; Masten et al., 1994). As a result, some suggest that the life stressors–psychopathology associations reported in much of the research are inflated.

Researchers have dealt with this measurement problem in a variety of ways. One approach is to study only uncontrollable, or fateful, stressors, those that occur independently of an individual's actions (Shrout et al., 1989). Findings using this method have been inconsistent, with some studies finding an association with psychological adjustment (DuBois, Felner, Brand, Adan, & Evans, 1992; Newcomb, Huba, & Bentler, 1986) and others not (Dubow, Tisak, Causey, Hryshko, & Reid, 1991; Gersten, Langner, Eisenberg, & Simcha-Fagan, 1977). A second approach examines the role of controllable and uncontrollable life stressors simultaneously, but here again the findings have been inconsistent. Cohen and his colleagues (Burt, Cohen, & Bjorck, 1988; L. H. Cohen et al., 1987) found that only controllable major stressors were related to subsequent psychological symptoms, whereas others have found this association for both controllable and uncontrollable stressors (Masten et al., 1994; Rowlison & Felner, 1988). Thus, the extent to which controllable and uncontrollable stressors are related to depressive symptoms remains unclear.

It should be noted that relying on research participants' reports of life stressors has, in and of itself, been called into question. In fact, any stressors self-report could be considered dependent in that it reflects what the individual perceives to be significant experiences (B. S. Dohrenwend et al., 1984; Rudolph et al., 2000). We argue that additional research using this type of measure is important for two reasons. First, the vast majority of previous studies, as well as many recent studies, have used this approach in spite of the methodological critiques (Cole, Nolen-Hoeksema, Girgus, & Paul, 2006; Kim, Conger, Elder, & Lorenz, 2003; Morales & Guerra, 2006). Second, the primary goal of this study is to contribute to a better understanding of the S-DS process, which is at least partially based on research using this method of life stressors measurement.

Alternatives to Social Causation Models

Important questions have been raised regarding the strength and direction of the life S-DS relationship suggested by social causation models. At least three alternate theory-based psychosocial models could represent the processes at play.

Although not generally acknowledged in the S-DS literature, an alternate unidirectional model can be derived from the mood congruent memory research. This research has established that an individual's mood is likely to influence the types of memories recalled. This *mood-congruent cognitive bias* model suggests that the association between depressive symptoms and reports of stressful life circumstances is due, at least in part, to the fact that people are more likely to recall negative memories when in a negative mood and positive memories when in a positive mood (for a review, see Blaney, 1986; see Figure 2a).

Mood congruence studies have used both observational and experimental designs. One type of observational design involves assessing participants' existing mood, having them learn novel material, and then comparing more and less depressed participants on the emotional valence of material recalled. These studies find that more depressed participants recall more negatively valenced material than nondepressed participants (Ingram, Smith, & Brehm, 1983; McDowall, 1984). Experimental studies in which researchers induce a depressed mood in the treatment group have also found evidence of mood-congruent cognitive bias in recall (Bower, 1981; Klaassen, Riedel, Deutz, & van Praag, 2002).

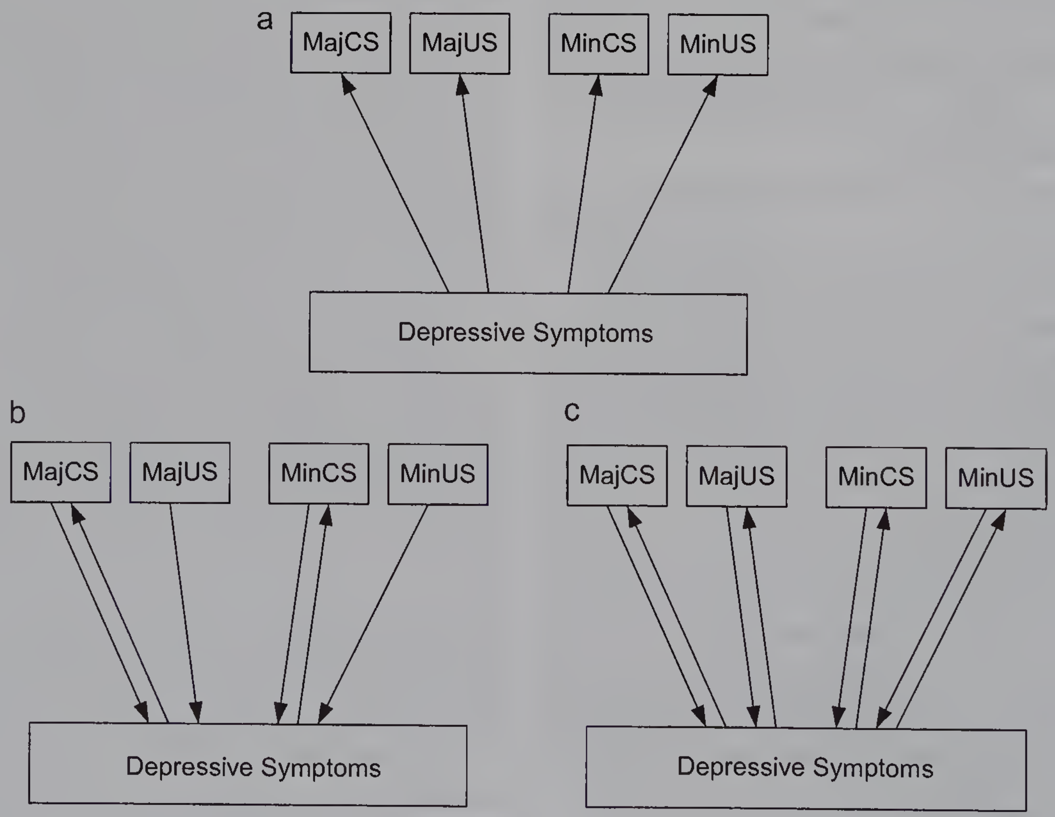

Figure 2. Heuristic models of the alternate theories.
Note. MajUS = major uncontrollable stressor; MinUS = minor uncontrollable stressor; MajCS = major controllable stressor; MinCS = minor controllable stressor.

Other researchers argue that unidirectional models do not account for the transactional relationships between individuals and their environments (Cicchetti, 1984; Felner & Felner, 1989; Sameroff & Mackenzie, 2003). An example of this type of transactional process is the following: The death of a parent causes an adolescent to become depressed; the resulting emotions and behaviors lead to an increase in stressors, such as interpersonal problems with friends, and these stressors cause the adolescent to become more depressed. Early research investigating transactional S-DS relationships compared the regression coefficient for a stressors-to-depressive symptoms effect (S → DS) estimated in one regression to the coefficient of a depressive symptoms-to-stressors effect (DS → S) estimated in a separate analyses, with some studies finding that the S → DS associations was stronger (DuBois et al., 1992; Pianta & Egeland, 1994) and others the reverse (L. H. Cohen et al., 1987).

Hammen and her colleagues are among those who propose a transactional S-DS model (Hammen, 1991, 1992a; Rudolph et al., 2000). While recognizing that depression may be triggered by stressful circumstances that a person cannot control, Hammen's (1991) *stress generation model* suggests that depressed people behave in ways that create stressful circumstances in their lives (see Figure 2b). Using an in-depth interview method designed to control for the influence of cognitive bias on event recall, she and her colleagues have found that depressed women and adolescents recall more controllable stressors, but not more uncontrollable stressors, than their nondepressed counterparts (Hammen, 1991; Rudolph et al., 2000).

Studies using self-report checklist measures of stressors have also found support for the stress generation theory (Cole et al., 2006; Kim et al., 2003). However, these studies did not account for the possibility that the stressors measures might include both controllable and uncontrollable stressors or the possibility that the DS → S associations might represent mood-congruent cognitive bias. In fact, in order to determine whether stress generation and/or cognitive bias account for significant DS → S paths, research must distinguish between controllable and uncontrollable stressors. Specifically, the presence of significant DS → S paths only for controllable stressors would support the conclusion that stress generation is at work. On the other hand, significant DS → S paths for uncontrollable stressors would indicate that mood-congruent cognitive bias is at work, as these stressors are not likely to result from stress generation. It should be noted that if mood-congruent cognitive bias is operating, it is likely to produce significant DS → S associations for both controllable and uncontrollable stressors, as its influence would apply to recall of both types of stressors. For research using self-report measures of stressors, determining what portion of the depressive symptoms-to-controllable stressors association is due to cognitive bias and what portion is due to stress generation would not be possible.

A second possible transactional model is a *fully transactional* model that simultaneously accounts for the processes suggested by all models discussed thus far: the contribution of life stressors to the development of depressive symptoms, the influence of current mood on one's recall of negative experiences, and the possibility that depressed individuals behave in ways that create stressful life circumstances (see Figure 2c). A formal test of whether the fully transactional model provides the best fit would contribute to our understanding of how life stressors influence the development of depressive symptoms in at least two important ways. First, it would demonstrate whether stress generation is the only transactional process operating or whether mood-congruent recall bias should be considered. Second, it would provide a rigorous test of the extent to which stressful life circumstances predict the development of depressive symptoms because any effects would demonstrate the S → DS effect net of stress generation and/or cognitive bias.

Current Study

The primary goal of the present study was to systematically estimate and compare the fit of six competing theory-based psychosocial models of the S-DS relationship that have been proposed in previous research. Furthermore, to address a central methodological critique of existing life stress research, we used measures of major and minor life stressors that distinguish between controllable and uncontrollable experiences in the estimation of the models.

Method

Sample

Data for this study come from the Adolescent Pathways Project (APP), a longitudinal study of youth attending public schools in Baltimore, MD; Washington, DC; and New York, NY (Seidman, 1991). The APP study was designed to apply an ecological framework to the study of adolescent development among ethnically diverse youth attending schools with high proportions of students from low-income families. In the 1st year of the study, we assessed participants' ($N = 907$) race/ethnic background by asking them to indicate whether they were White/not Hispanic (19%), Black/not Hispanic (32%), Hispanic (40%), Asian (5%), or more than one race/ethnic group (4%). In the 2nd year of the study, we asked participants to describe in their own words their families' ethnic background(s) and found that most Hispanic students' families were originally from Puerto Rico or the Dominican Republic, most Black students' families were originally from the Caribbean islands or were African American, and most White students' families were originally from Italy or Greece. Fifty-four percent of the participants were female and the average age at Wave 1 was 11.40 years ($SD = 0.92$), with the large standard deviation representing the fact that the sample spanned two grades. An examination of 1990 U.S. Census data for the 707 New York participants indicated that the majority lived in census tracts where at least 20% of the households had incomes below the federal poverty threshold. Schools with a minimum of 60%–80% of the student body eligible for reduced price or free lunch were targeted for participant recruitment. Within these schools, all students in the grade prior to the transition to a middle grades school were contacted for participation in the study (i.e., the fifth or sixth grade, depending on school grade structure).

Active parental consent was required for participation. APP staff provided a study description and consent form (in both English and Spanish) for teachers to send home with children, which children were to give to parents and return to school. A follow-up notice was provided to teachers approximately 1 week later. The 907 early adolescents for whom valid data were collected at Wave 1 represented 38% of the adolescents recruited for participation. We believe it is likely that the numerous steps and individuals involved in the active consent procedure contributed to this participation rate. Sixty-four ($N = 581$) percent of the original sample participated in all three waves of data collection and 22% participated in two waves of data collection (Wave 1 and either Wave 2 or 3, $N = 183$).

Attrition analyses comparing adolescents who participated at all three waves to those who are missing one or more waves of data indicate that the two groups differed in terms of race/ethnic group composition and age, but that the effect sizes were small. A comparison of the three largest race/ethnic groups showed that a larger percentage of the White adolescents (74%) participated at all three waves than Latino (66%) or Black (56%) adolescents, $\chi^2(2) = 16.79$, $p < .001$. However, a binary logistic regression in which retention at all three waves (vs. missing any wave) was regressed on two variables indicating whether a participant was Black or White (with the largest group, Hispanic, as the reference group) indicated that only 2% of the variance in attrition status is associated with an adolescent's race/ethnicity. In terms of age, adolescents missing one or more waves of data were slightly older than those with data for three waves ($M = 11.49$ years, $SD = 1.00$ and $M = 11.35$, $SD = 0.86$, respectively), $t(902) = 2.18$, $p < .01$. The effect size for this age difference was small, Cohen's $d = .15$ (J. Cohen, 1988). There was not a significant difference in the gender composition of the two groups, $\chi^2(1) = 3.32$, *ns*. We present the attrition analyses for study variables after describing the measures.

The APP collected Wave 1 data in the spring of 1988, which was participants' last year of elementary school. Waves 2 and 3 data collection took place approximately 1 and 2 years later, respectively. Small teams of APP staff from diverse racial and ethnic backgrounds collected data in group settings at schools. Instructions and questions were read aloud to the group while staff members circulated throughout the room to answer participants' questions and spot-check responses to measures with more complicated directions.

Measures

Major stressors. Respondents reported negative major stressors using a checklist measure consisting of 17 items adapted from Johnson and McCutcheon's (1980) Life Events Checklist and 9 additional items representing stressors that that inner-city adolescents might experience. Participants indicated whether they had experienced each event in the past year and scores represent the number of stressors adolescents reported. We describe the procedure for distinguishing controllable and uncontrollable items below. Because stressors scales are designed to assess experiences that may occur independently from each other, it is not appropriate to estimate the internal consistency of these measures (Hoffman & Su, 1997; Kim et al., 2003).

Minor stressors. Respondents reported minor stressors using the 27-item Daily Hassles Scale (Seidman et al., 1995), which consists of items adapted from Rowlison and Felner's (1988) daily hassles measure and additional items developed to assess resource-related and neighborhood stressors. Respondents rated each stressor on a 5-point scale, indicating either that the stressor, or hassle, *had not occurred in the past* *year* (1), *or that it had occurred and was either not a* (2), *a little bit* (3), *a moderate* (4), or *a very big* (5) hassle. We dichotomized each item score as either a nonoccurrence (scores of 1 or 2) or an occurrence (scores of 3, 4, or 5) and computed a composite score of the number of minor stressors experienced in the past month. The procedure used to identify controllable and uncontrollable minor stressors is described below. These scales are designed to assess experiences that may occur independently from each other and it is not appropriate to estimate their internal consistency.

Depressive symptoms. The depressive symptoms scale consists of 14 items from Achenbach and Edelbrock's (1987) Youth Self-Report. Respondents reported whether each item was *not true* (0), *somewhat or sometimes true* (1), or *very true or often true* (2) for them in the past 6 months. Internal consistency was adequate (αs = .84, .84, and .86 in Waves 1, 2, and 3, respectively).

Identifying Controllable and Uncontrollable Stressors

Because neither stressors measure was designed to distinguish controllable and uncontrollable stressors, we conducted a preliminary study to inform this distinction. We based our methodology on that used by B. S. Dohrenwend et al (1984) in their research investigating conceptual and operational distinctions for measurements of psychological symptoms, major stressors, and minor stressors.

A convenience sample of psychologists and advanced psychology graduate students (N = 27, 63% White, 19% Asian, 11% Black, and 7% Hispanic) rated the extent to which adolescents may play a role in experiencing each of the negative major and minor stressor items. Interspersed with the stressor items were 10 anchor items designed to clearly represent either a controllable event (e.g., *watched TV, read a magazine*) or an uncontrollable event (e.g., *it snowed*). Respondents rated items using a 5-point scale, ranging from 1 (*an adolescent almost certainly plays some role in this event*) through 5 (*an adolescent almost certainly plays no role in this event*), with 3 (*an adolescent may or may not play some role in this event*) as the midpoint.

We conducted one-sample t tests, using the midpoint (3.0) as the criterion, to determine whether an item was controllable or uncontrollable. We classified items with means significantly greater than 3.0 as uncontrollable stressors and those with means significantly less then 3.0 as controllable. This process identified 6 controllable major stressor items and 17 uncontrollable items, and eliminated the 3 major stressor items with means not significantly different from 3.0. For minor stressors, we classified 9 items as controllable, 11 as uncontrollable, and eliminated 7 with means not significantly different from 3.0. (A full list of all items, their means and standard errors, and classifications is available from the authors.) Means for the items designed to anchor ends of the scale were significantly different from 3.0 in the directions anticipated, with means for the controllable items below 1.5 and means for the uncontrollable items equal to 5.0.

Descriptive analyses for the new controllable and uncontrollable subscale scores showed a low endorsement rate for the controllable major stressors measures at all three waves (e.g., became pregnant, expelled from school). This construct was excluded from all subsequent analyses. Means and standard deviations of all study variables are reported in Table 1.

Additional Attrition Analyses Examining Study Variables

We conducted additional attrition analyses on Wave 1 scores of all study variables comparing adolescents who participated in all waves with those who did not. In order to adjust for the two demographic characteristics significantly associated with attrition (identified above), we conducted a 2 × 3 (Attrition Group × Race/Ethnic Group) analysis of covariance with age entered as a covariate. There were significant differences between the two attrition groups on two of the four study variables. The depressive symptoms score was lower for the group that participated in all three waves than for the group missing one or two waves of data ($M_{\text{adjusted}} = 0.47$, $SE = .02$ compared to $M_{\text{adjusted}} = .52$, $SE = .02$), $F(1) = .4.52$, $p < .05$, $\eta^2 = .01$. There was also a significant difference between the two groups for major uncontrollable stressors, with the group participating in all three waves reporting fewer stressors than the group that did not ($M_{\text{adjusted}} = 1.25$, $SE = .06$ compared to $M_{\text{adjusted}} = 1.48$, $SE = .09$), $F(1) = 4.06$, $p < .05$, $\eta^2 = .005$). In both cases, the percent of variance explained was less than 1%.

Results

All structural equation models (SEMs) were estimated using the full information maximum likelihood (FIML) estimation method available in Mplus, version 4.1 (Muthén & Muthén, 2006). We chose FIML because this method of estimation uses all information in the observed data, including cases with missing data. This approach to handling missing data is preferable to listwise deletion of cases, which

results in both the loss of potentially valuable information and reduced statistical power (Schafer & Graham, 2002). We conducted all analyses a second time after imputing missing values using the expectation maximization algorithm and found that the results were essentially the same for the two methods of handling missing data. We report the results using FIML estimation below.

Given this study's large sample size, the chi-square statistic is not diagnostic of model fit and we used the two-index strategy recommended by Hu and Bentler (1998, 1999) instead. The two fit indices we used were the standardized root mean square residual (SRMR), which Hu and Bentler recommend for all SEM analyses, and the root mean square error of approximation (RMSEA) because it is sensitive to complex model misspecification (Hu & Bentler, 1998). Both indices estimate the residual between the estimated covariance matrix and the sample covariance matrix. Hu and Bentler (1998) suggest .08 as the cutoff value for SRMR and .06 for RMSEA. We used the chi-square difference statistic (χ^2_{diff})—the difference between the chi-square of two models—to compare the fit of nested models and the Akaike information criterion (AIC) to compare the fit of nonnested models (Kline, 2005).

Each of the models contains a set of identical paths that estimate the autoregressive associations and certain residual covariance estimates. The autoregressive paths represent the stability of each variable across the three data points. We allowed the residuals for the controllable and uncontrollable minor stressors scores to covary within each wave because they were originally from the same instrument. The means, standard deviations, and intercorrelations of all model variables appear in Table 1. (Given our use of FIML estimation, these correlations are not technically those of the data used in the SEM analyses.)

Social Causation Models

Independent effects model. This model included direct S → DS paths for all stressors at each wave. The model does not provide an adequate fit of the data, SRMR = .099, RMSEA = .072. Table 2 presents the fit statistics for this and all subsequent models, and Table 3 presents the estimated coefficients for all models.

Although it is not generally meaningful to interpret a model that does not adequately fit the data, we will briefly review this model because it is most like the analysis conducted in much of the S-DS research. It is important to note, however, that even with this model's similarities to analyses in previous studies, it is considerably more conservative because it predicts change in depressive symptoms using change in stressors not the overall level of stressors (i.e., a single wave of stressors data).

The autoregressive coefficients in this model demonstrate that there is considerable stability in stressors and depressive symptoms over the course of the study, with most of the βs representing moderate to strong associations. Regarding the S → DS paths, all three stressors are significantly related to depressive

symptoms at Wave 1, a finding that is in line with existing cross-sectional studies. The coefficients for the S→DS paths in Waves 2 and 3 suggest that only changes in the minor stressors are positively associated with changes in depressive symptoms. Although the nonsignificant major stressors – depressive symptoms paths appear to contradict much of the published research regarding major life stressors, this may be due to the fact that the change is being modeled at Waves 2 and 3 not the statistical relationship with a single cumulative measure.

For the independent effects model and all subsequent models, we anticipated that the S-DS association would be strongest between depressive symptoms and the most recently experienced stressors. By estimating the association between stressors and depressive symptoms reported at the same data collection point, we were in effect examining the association between stressors experienced in the preceding year and recent depressive symptoms. However, to investigate whether the models should include lagged paths between stressors experienced in the prior year and recent depressive symptoms, we estimated two alternate versions of the model. The first model estimated the associations between previously experienced stressors (e.g., Wave 1) only and change in depressive symptoms (e.g., Wave 2). This fit of this model was worse than that of model estimating the S-DS association for recently occurring stressors. The second model added the lagged S→DS paths to the original independent effects model, so that the model included both the lagged and the concurrent paths. The fit of this model was also inferior to the originally estimated model. Based on these two analyses, we determined that modeling paths between the measures of most recent stressors and depressive symptoms is the best approach for testing the social causation theories. (Model fit statistics and estimated coefficients for the alternate models may be obtained from the authors.)

Fully mediated model. For this model, we removed the paths from uncontrollable major stressors to depressive symptoms at each wave and replaced them with mediated pathways through each of the minor stressors. In spite of the multiple structural differences in this model compared to the independent effects model, the degrees of freedom have decreased only by one (44 – 43). This is because the model simultaneously gained three degrees of freedom from removing the major stressors to depressive symptoms paths at each wave, but lost four through the addition of paths from uncontrollable major stressors to the two minor stressors measures at Waves 2 and 3. It should be noted that because SEMs estimate the noncausal associations (correlations) among all purely exogenous variables, changing the paths at Wave 1 from noncausal to causal did not effect the degrees of freedom for this part of the model. The fit of the mediated model is significantly better than the independent effects model, $\chi^2_{\text{diff}}(1) = 28.07, p < .001$, but does not provide an adequate fit to the data, SRMR = .086, and RMSEA = .067.

Partially mediated model. For the partially mediated model, we added direct paths from uncontrollable major stressors to depressive symptoms at each wave. The model does not provide an adequate fit of the data, SRMR = .085 and RMSEA = .068. However, the fit is significantly better than the fully mediated

model, $\chi^2_{\text{diff}}(3) = 13.20, p < .001$, in spite of the fact that all the direct paths from uncontrollable major stressors are not significantly different from zero. In fact, a closer examination of the mediated models suggests that mediation is not occurring even though both models provide a better fit to the data than the independent effects model. First, even in the independent effects model, the Waves 2 and 3 direct paths from uncontrollable major stressors to depressive symptoms were not statistically significant. Second, the coefficients from the minor stressors to depressive symptoms remain essentially the same across the three social causation models, indicating that the strength of their associations with DS does not increase over the unique contributions estimated in the independent effects model.

Mood-Congruent Cognitive Bias Model

The structure of the cognitive bias model is essentially the opposite of the independent effects social causation model: all S→DS paths were removed and replaced with DS→S paths. To estimate a model that would be similar to the independent effects model except for the direction of the S-DS paths, we estimated the covariance between the residuals of Wave 1 stressors. This was necessary because as exogenous variables in the independent effects models they were automatically estimate.

In contrast to the social causation models, this model provides an adequate fit to the data, SRMR = .056 and RMSEA = .040. Because this model is not nested with the social causation models, we used the AIC to compare model fit. The lower AIC statistic for the mood-congruent cognitive bias model indicates that it provides a better fit to the data than any of the social causation models, for example, $\text{AIC}_{\text{cognitive bias}} = 26{,}313.13$ and $\text{AIC}_{\text{independent effects}} = 26{,}717.29$. All the coefficients for the DS→S paths are statistically significant, with standardized coefficients ranging from 12 to .18 for major stressors and .30 to .45 for minor stressors. While changing the direction of structural paths in an SEM can, under particular circumstances, produce an equivalent model, this is not the case when changing the direction of the S-DS paths to specify the mood-congruent cognitive bias model. Equivalent models are those that produce the exact same estimated covariance matrix and fit statistics even though some of the structural paths in the models are different. For a structural change in a model to produce an equivalent model, the predictors of the initially endogenous variable (e.g., DS in the independent effects model) must include the predictors of the exogenous variable in the original model (e.g., S in the independent effects model). Only under these circumstances will the respecified model produce an identical estimate of the covariance matrix (Kline, 2005; Lee & Hershberger, 1990).

As we did in the case of the independent effects model, we conducted an additional set of analyses in order to rule out the possibility that including paths representing lagged associations between depressive symptoms and stressors would result in a better fitting model. We followed the same procedure to test the alternate models that we used for the independent effects model: The first model estimated the associations between previously reported depressive symptoms (e.g., Wave 1) and change in stressors (e.g., Wave 2), and the second model added the lagged paths to the original model. The fit of both models was worse than that of the original model. (Model fit statistics and estimated coefficients for the alternate models may be obtained from the authors.)

Stress Generation Model

The stress generation model includes S→DS paths from all stressors and DS→S paths only for controllable minor stressors (to represent the generation of controllable stressors). Although the DS→S paths representing stress generation are statistically significant, this model does not provide an adequate fit to the data, SRMR = .084 and RMSEA = .065. Given that all the DS→S paths were significant in the mood-congruent cognitive bias model, it is not surprising that the stress generation model, which excludes four of those paths, does not fit as well.

Fully Transactional Model

The fully transactional model integrates components of the mood-congruent cognitive bias, stress generation, and independent effects social causation models. (We did not include the mediation paths because the results did not demonstrate mediation.) At Waves 2 and 3, the fully transactional model includes S→DS paths from all stressors and DS→S paths to all stressors. At Wave 1, we included the unidirectional paths representing the mood-congruent cognitive bias model. The model provides an adequate fit of the data, SRMR = .052 and RMSEA = .051, and the fit of this model is significantly better than that of the mood-congruent cognitive bias model, $\chi^2_{\text{diff}}\ (6) = 14.95, p < .05$, indicating that it provides the best fit of all models examined.

As was the case with the mood-congruent cognitive bias model, all the DS→S paths are significant, with most having a moderate effect size. Only two of the S → DS paths are statistically significant, both in Wave 2, which is the 1st year in a junior high/middle school for all study participants. The significant positive S → DS path for minor uncontrollable stressors indicates that experiencing an increase in minor uncontrollable hassles predicts an increase in depressive symptoms for these adolescents, net of the DS → S effect, $\beta = .15$. The standardized path coefficient for the S → DS path for uncontrollable major stressors at Wave 2 has changed from essentially nil (−.01) in the social causation models to −.15.

Discussion

The primary goals of this study were to compare the fit of six theory-based, psychosocial models of the stress–depressive symptoms association and to address a central methodological critique of this line of research—that self-report life stressors measures may be confounded with psychological symptoms. Our SEM analyses demonstrated that the social causation models, which represent the most common theoretical approach to studying the S-DS association, do not provide an adequate fit to the data in spite of the fact that most of the S → DS paths were statistically significant. Had we used an alternate data analytic method, such as ordinary least squares regression, and examined only this theoretical model, we could have incorrectly concluded that the process accounting for the S-DS associations is social causation alone. Only when we modeled the influence of mood on recall—either alone in the mood-congruent cognitive bias model or in the fully transactional model—did the estimated models fit the data adequately.

We will discuss the findings from the social causation models in order to compare our findings to those from previous research. The findings in the cross-sectional (Wave 1) portion of these models were similar to those of previous research in that the S → DS paths were significant for major and minor stressors. Comparing our longitudinal findings to previous research is less straightforward because the structure of the longitudinal components of our models tested the extent to which a *change* in stressors predicts a *change* in depressive symptoms, although most previous longitudinal S-DS studies have predicted depressive symptoms using only a single, cumulative measure of stressors: either a prior report of stressors (Hammen, Burge, & Adrian, 1991; Morales & Guerra, 2006; for a review, see Grant, Compas, Thurm, McMahon, & Gipson, 2004) or a recent report of stressors (Compas, Slavin, Wagner, & Vannatta, 1986; DuBois et al., 1992, 1994; Nolen-Hoeksema & Girgus, 1994). Research using either design has consistently found that major and minor stressors predict increases in depressive symptoms. Our approach was considerably more stringent in that we examined whether *changes* in stressors predict changes in depressive symptoms.

Given that many previous studies have found either a direct or mediated relationship between major stressors and depressive symptoms, the fact that our models did not was unexpected. There are at least three explanations for this finding. One possibility is that this more stringent test demonstrates that a single, cumulative measure of major stressors predicts change in depressive symptoms, but an increase in major stressors does not. A second possibility is that the S-DS associations found in other studies were due to the fact that the stressors measures included items confounded with psychological adjustment. A third possibility is that the magnitude of the major stressors → DS association is smaller for low-income, urban adolescents than for the adolescent participants in previous studies.

The most important finding from the social causation models is that they do not provide an adequate fit of the data even though almost all estimated parameters were statistically significant. This finding demonstrates that examining only social causation models of the S-DS process is not appropriate when using self-report measures, and we suggest that any S-DS study incorporating a social causation perspective should go on to rule out other possible explanations for the S-DS association. Significant S → DS paths are not, in and of themselves, an adequate stopping place for these investigations. The fact that the mood-congruent cognitive bias model provided a markedly better fit of the data indicates that S-DS research must take into account the likelihood that life stressors reports reflect participants' mood.

In light of the fact that several recent studies have found support for stress-generation models of the S-DS association (Cole et al., 2006; Hammen, 1991; Kim et al., 2003; Rudolph et al., 2000), one might question our finding that the stress generation model did not fit the data. We suggest that important methodological differences in our model account for the divergent results, and that our findings make important theoretical contributions to understanding the S-DS process. As we discussed earlier, without distinguishing between and including both controllable and uncontrollable stressors, it is not possible to conclude that stress generation per se is responsible for significant DS → S paths. In order to conclude that only stress generation is at play requires demonstrating that depressive symptoms *do* predict increases in controllable stressors and *do not* predict increases in uncontrollable stressors. This was our approach. The stress generation model included DS→S paths for controllable stressors only and did not provide an adequate fit to the data, these paths were significant. The fully transactional model included DS→S paths for all stressors, found that all of these paths were significant, and provided an adequate fit to the data.

Although the stress generation model we estimated did not fit the data, we do not rule out the validity of this model. As discussed earlier, there are alternate approaches to measuring life stressors that distinguish between controllable and uncontrollable stressors, with the work Hammen, Rudolph, and their colleagues exemplifying this approach (Hammen, 1991; Rudolph et al., 2000). In these studies, researchers conducted interviews designed to elicit details about the context in which stressful experiences occurred, and then assessed the degree to which a typical person would be effected by such an experience (how stressful the event was) and the degree to which the participant contributed to the event's occurrence (how controllable the event was). Their assumption is that these stressors measures do not include mood-congruent cognitive bias and, as a result, do not need to statistically model this process. Using this method, Hammen and her colleagues have consistently found that depressed individuals are more likely to experience interpersonal, dependent, major stressors (Hammen, 1991; Rudolph et al., 2000).

A second reason not to rule out the validity of the stress generation model is that the self-report checklist stressors measures we used did not allow us to determine the extent to which the DS→controllable stressors paths represent mood-congruent cognitive bias and to what extent they represent stress generation. It is possible that these paths represent both processes.

Although the stress generation model did not provide an adequate fit to the data in this study, our findings regarding the S-DS process are similar to those of Hammen and her colleagues in that we demonstrate one way in which cognition functions in the stress-depression process (Hammen, 1992b; Rudolph, 2002; Rudolph & Hammen, 1999; Rudolph et al., 2000). They propose that children who encounter a great deal of uncontrollable stress early in their lives develop the belief that they cannot exert control over their environments, which results in the development of negative cognitive styles. Manifestations of this are the negative interpretation of events and the tendency to be more likely to recall the negative experiences in one's life. It is important to note that depressed individuals are not constructing negative memories of events that never happened, but that they are more likely to both remember these experiences and interpret them more negatively.

Before we discuss the results of the fully transactional model, we will address the composition of the sample in this study, as this informs our discussion of the model. As is often the case in development studies, adolescents who participated in this study are not representative of the population of adolescents. In fact, most previous studies of the S-DS process have focused on the experiences of White adolescents (Clements, 2003). The overarching goal of the sampling strategy used by the APP study, from which data for the current study were drawn, was to address the fact that developmental scientists have much to learn about the factors that promote and hinder positive academic and social-emotional development among low-income urban adolescents. Furthermore, the group that participated in the study represents the subset of this population with characteristics (whatever they may be) that enabled them to obtain their parents' consent and to participate.

Although we recognize that the sample in this study represents a selected group of adolescents, we anticipate that the mood-congruent cognitive bias effect is generalizable to adolescents from other socioeconomic and demographic backgrounds because previous experimental and quasi-experimental studies have demonstrated that it is a robust phenomenon. Although, as for any finding, replication in studies of other adolescent populations is necessary.

We are more hesitant to draw strong conclusions about the S→DS effects. The nonsignificance and small effect size of many of these coefficients may be due to a number of factors. One issue, as discussed earlier, is that the sample is not representative. It is possible that the findings of the fully transactional model are an accurate representation of the S→DS process for this particular population of adolescents. However, without other studies, using this design we cannot know whether the S→DS processes identified here are unique to this group of adolescents. It could also be that early adolescence is not the developmental period during which life stressors are most likely to cause depressive symptoms. For example, it may be that the relationship between stressful life experiences and depressive symptoms is stronger at earlier developmental periods, such as childhood, and that persistent symptoms cause adolescents to perceive their experiences more negatively. It is also possible that the S→DS effects cannot be detected due to measurement error. For example, Shrout et al. (1989) point out that the impact of any stressor reported on checklist measures may vary considerably for an individual depending on context and circumstances in which the stressor occurs. Furthermore, it is important to note that the fully transactional model provided a significantly better fit to the data than the cognitive bias model, suggesting that the S→DS paths are a meaningful component of the model and processes that research should continue to explore.

An additional consideration is that the S→DS path coefficients are smaller than the DS→S coefficients due to the structure of the analyses. Because multiple stressors measures are used to predict depressive symptoms, the paths reflect each stressor's unique association with symptoms. In contrast, the paths representing the effect of depressive symptoms on stressors are not adjusted for shared variance with other variables. In other words, the S→DS coefficients are smaller because, at least in part, these paths are adjusted for their shared variance with the other stressors and represent each stressor's independent association with depressive symptoms.

Limitations

As we have discussed earlier, there are several aspects of this study that may limit the generalizability of the findings. One is that the sample is not representative of adolescents as a whole. Second, even though this study was designed to address the methodological problems regarding life stressors measurement, the methods we used may not have ruled out other sources of measurement error, such as the possibility that the impact of certain stressors varied considerably for different individuals. It is also possible that our checklist measures did not include all the potential stressful circumstances operating in these adolescents' lives. Such shortcomings would effect the estimates of the S-DS associations. In addition, the fact that all data are self-report increases the possibility that estimates may be biased due to method variance.

It is relevant to note, however, that adopting any particular method for assessing stressful life circumstances does not eliminate concerns regarding measurement validity. There has been considerable debate regarding whether normative-based measures (which specify the normative stressfulness and disruptiveness of events) or appraisal-based measures (which allow participants to indicate the degree of event stressfulness) are more appropriate (Compas, 1987; B. P. Dohrenwend, Shrout, Link, Skodol, & Martin, 1986; Lazarus & Folkman, 1986). Normative measures are criticized because they are subject to event variability within category, whereas appraisal measures are criticized because the reports of event stressfulness could be confounded with existing psychological adjustment.

Directions for Future Research

There are several possible directions for future research. As we discussed earlier, most previous life stressor research among adolescents has focused on the experience of White adolescents, whereas most participants in this study were from ethnic minority groups. Future research should examine whether mood-congruent recall bias operates in a similar way for various subgroups of adolescents. Research is also needed to investigate the extent to which experiencing different types of life stressors leads to depressive symptoms for different subgroups of adolescents after accounting for the influence of mood-congruent cognitive bias.

Another way in which this research could be extended would be to further distinguish between different types of stressors rather than rely on the global measures used in this and many other studies. One possibility would be to distinguish between interpersonal and noninterpersonal stressors, as advocated by Rudolph and Hammen (1999). A second possibility would be to create domain-specific measures of major and minor stressors to determine whether adolescents are more (or less) vulnerable to stressors in a particular domain (e.g., home, school, peers, and/or neighborhood).

In this same vein, new approaches to measuring life stressors could be applied. To date, stressors measures assessed through both checklists and interviews have been computed as the total number of stressors experienced. One alternative would be to estimate continuous latent variables of stressors, which could reduce the measurement error that is likely present in the summed variables currently being used. A second possibility would be to apply a type of classification technique, such as latent class analysis. This would enable researchers to examine whether experiencing a certain set of stressors results in an increased likelihood that an adolescent will become more depressed. It will be important that any new measurement strategy investigate the extent to which stressors measures are subject to mood-congruent recall bias.

Notwithstanding the issues to be addressed in future research, we believe that this study demonstrates a valuable approach to studying the S-DS process. Our findings call attention to the necessity of addressing the potential role of mood-congruent cognitive bias in stressors recall, as well as the value of systematically comparing multiple, competing theoretical models.

Arguing on the Computer, Deanna Kuhn, Wendy Goh, Kalypso Iordanou, and David Shaenfield.

Neighborhood Poverty and Early Transition to Sexual Activity in Young Adolescents: A Developmental Ecological Approach, Veronique Dupere, Eric Lacourse, J. Douglas Willms, Tama Leventhal, and Richard E Tremblay.

Infants' Use of Lexical-Category-to-Meaning Links in Object Individuation, D. Geoffrey Hall, Kathleen Corrigall, Mijke Rhemtulla, Eleanor Donegan, and Fei Xu.

Searching and Planning: Young Children's Reasoning About Past and Future Event Sequences, Kerry McColgan and Teresa McCormack.

Young Children's Recognition of the Intentionality of Teaching, Margalit Ziv, Ayelet Solomon, and Douglas Frye.

Changes in the Relation of Self-Efficacy Beliefs and Behaviors Across Development, Pamela E. Davis-Kean, L. Rowell Huesmann, Justin Jager, W. Andrew Collins, John E. Bates, and Jennifer E. Lansford.

Categories Influence Predictions About Individual Consistency, Marjorie Rhodes and Susan A. Gelman.

The Influence of Race and Gender on Children's Conversations and Playmate Choices, Patrick Leman and Virginia Lam.

Where's the Essence? Developmental Shifts in Beliefs About the Nature of Essential Features, George Newman and Frank Keil.

Profiles of Disruptive Behavior Across Early Childhood: Contributions of Frustration Reactivity, Physiological Regulation, and Maternal Behavior, Kathryn A. Degnan, Susan D. Calkins, Susan P. Keane, and Ashley L. Hill.

Development of Emotional and Behavioral Regulation in Children Born Extremely and Very Preterm: Biological and Social Influences, Caron Clark, Lianne Woodward, John Horwood, and Stephanie Moor.

Neural Processing of Eye Gaze and Threat-Related Emotional Facial Expressions in Infancy, Stefanie Hoehl and Tricia Striano.

Perception of Dynamic and Static Audiovisual Sequences in 3- and 4-Month-Old Infants, David Lewkowicz.

Don't Teach Children 2 + 2 Is Equal to 4: Typical Arithmetic Problems Hinder Learning of Mathematical Equivalence, Nicole McNeil.

Development of 3D Object Completion in Infancy, Kasey C. Soska and Scott P. Johnson.

Developmental Trajectories of Sex-typed Behavior in Boys and Girls: A Longitudinal Population Study of Children Aged 2½ to 8 Years, Susan Golombok, John Rust, Karyofyllis Zervoulis, Tim Croudace, Jean Golding, and Melissa Hines.

Gene-Environment Contributions to the Development of Infant Vagal Reactivity: The Interaction of Dopamine and Maternal Sensitivity, Cathi Propper, Ginger A. Moore, W. Roger Mills-Koonce, Carolyn Tucker Halpern, Ashley Hill, Susan D. Calkins, Mary Anna Carbone, and Martha Cox.

Maternal Socialization of Positive Affect: The Impact of Invalidation on Adolescent Emotion Regulation and Depressive Symptomatology, Marie B. H. Yap, Nicholas Allen, and Cecile D. Ladouceur.

Children's Insecure Representations of the Interparental Relationship and Their School Adjustment: The Mediating Role of Attention Difficulties, Patrick T. Davies, Meredith J. Woitach, Marcia A. Winter, and E. Mark Cummings.

Fetal Substance Exposure and Cumulative Environmental Risk in an African American Cohort, Chie Yumoto, Sandra Jacobson, and Joseph Jacobson.

Longitudinal Analysis of Intrinsic Motivation and Competence Beliefs: Is There a Relation Over Time?, Birgit Spinath and Ricarda Steinmayr.

Limitations in Four-Year-Old Children's Sensitivity to the Spacing Among Facial Features, Catherine Mondloch and Kendra Thomson.

Postural and Object-Oriented Experiences Advance Early Reaching, Object Exploration, and Means-End Behavior, Michele A. Lobo and James C. Galloway.

Stability and Change of Moral Disengagement and Its Impact on Aggression and Violence in Late Adolescence, Marinella Paciello, Roberta Fida, Carlo

Tramontano, Catia Lupinetti, and Gian Vittorio Caprara.

Automatic Activation of Adolescents' Peer-Relational Schemas: Evidence From Priming With Facial Identity, Lauri Nummenmaa, Kätlin Peets, and Christina Salmivalli.

Effects of Aggresssion on Achievement: Does Conflict With the Teacher Make It Worse?, Deborah Stipek and Sarah Miles.

Effects of Family Violence on Psychopathology Symptoms in Children Previously Exposed to Maltreatment, Andrea Maikovich, Sara Jaffee, Candice Odgers, and Robert Gallop.

The Family Check-Up With High-Risk Indigent Families: Preventing Problem Behavior by Increasing Parents' Positive Behavior Support in Early Childhood, Thomas Dishion, Daniel Shaw, Arin Connell, Frances Gardner, Chelsea Weaver, and Melvin Wilson.

Children's Cortisol and the Quality of Teacher–Child Relationships in Child Care, Jared A. Lisonbee, Jacquelyn Mize, Amie Lapp Payne, and Douglas A. Granger.

Time Course of Visual Attention in Infant Categorization of Cats Versus Dogs: Evidence for a Head Bias as Revealed Through Eye Tracking, Paul C. Quinn, Matthew M. Doran, Jason E. Reiss, and James E. Hoffman.

Early Histories of School-Aged Children With Attention-Deficit/Hyperactivity Disorder, Irene M. Loe, Maria D. Balestrino, Randall A. Phelps, Marcia Kurs-Lasky, Diego Chaves-Gnecco, Jack L. Paradise, and Heidi M. Feldman.

Direct and Indirect Aggression: A Meta-Analytic Review of Gender Differences, Intercorrelations, and Relations to Maladjustment, Noel A. Card, Brian D. Stucky, Gita M. Sawalani, and Todd D. Little.

Children's Responses to Interparental Conflict: A Meta-Analysis of Their Associations With Child Adjustment, Kimberly A. Rhoades.

The Social Ecology of Adolescent Alcohol Misuse, Susan Ennett, Vangie A. Foshee, Karl E. Bauman, Andrea Hussong, Robert Faris, John Hipp, L i Cai, Robert DuRant, and Heathe Luz McNaughton Reyes.

HOW INFANTS KNOW MINDS

VASUDEVI REDDY

Most psychologists claim that we begin to develop a "theory of mind"—some basic ideas about other people's minds—at age two or three, by inference, deduction, and logical reasoning. But does this mean that small babies are unaware of minds? That they see other people simply as another (rather dynamic and noisy) kind of object? This is a common view in developmental psychology. Yet, as this book explains, there is compelling evidence that babies in the first year of life can tease, pretend, feel self-conscious, and joke with people. Using observations from infants' everyday interactions with their families, Vasudevi Reddy argues that such early emotional engagements show infants' growing awareness of other people's attention, expectations, and intentions.

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and ... are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www.srcd.org/webposting.html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org/CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all co-authors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (5th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Blackwell Publishing, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Incoming Editor, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Best Practices in Quantitative Methods for Developmentalists—*Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

Foundations of Self-Awareness: An Exploration Through Autism—*R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

Our Children Too: A History of the Black Caucus of the Society for Research in Child Development, 1973–1997—*Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

Parental Support, Psychological Control, and Behavioral Control: Assessing Relevance Across Time, Culture, and Method—*Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

Being Hurt and Hurting Others: Children's Narrative Accounts and Moral Judgments of Their Own Interpersonal Conflicts—*Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

Childhood Sexual Assault Victims: Long-Term Outcomes After Testifying in Criminal Court—*Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

The Emergence of Social Cognition in Three Young Chimpanzees—*Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

Trajectories of Physical Aggression From Toddlerhood to Middle Childhood: Predictors, Correlates, and Outcomes—*NICHD Early Child Care Research Network* (Serial No. 278, 2004).

Constraints on Conceptual Development: A Case Study of the Acquisition of Folkbiological and Folksociological Knowledge in Madagascar—*Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

Origins and Early Development of Human Body Knowledge—*Virginia Slaughter, Michelle Heron, Linda Jenkins, and Elizabeth Tilse* (Serial No. 276, 2004).

Mother – Child Conversations About Gender: Understanding the Acquisition of Essentialist Beliefs—*Susan A. Gelman, Marianne G. Taylor, and Simone P. Nguyen* (Serial No. 275, 2004).

The Development of Executive Function in Early Childhood—*Philip David Zelazo, Ulrich Müller, Douglas Frye, and Stuart Marcovitch* (Serial No. 274, 2003).

Personal Persistence, Identity Development, and Suicide: A Study of Native and Non-native North American Adolescents—*Michael J. Chandler, Christopher E. Lalonde, Bryan W. Sokol, and Darcy Hallett* (Serial No. 273, 2003).

Personality and Development in Childhood: A Person-Centered Approach—*Daniel Hart, Robert Atkins, and Suzanne Fegley* (Serial No. 272, 2003).

How Children and Adolescents Evaluate Gender and Racial Exclusion—*Melanie Killen, Jennie Lee-Kim, Heidi McGlothlin, and Charles Stangor* (Serial No. 271, 2002).

Child Emotional Security and Interparental Conflict—*Patrick T. Davies, Gordon T. Harold, Marcie C. Goeke-Morey, and E. Mark Cummings* (Serial No. 270, 2002).

The Developmental Course of Gender Differentiation: Conceptualizing, Measuring, and Evaluating Constructs and Pathways—*Lynn S. Liben and Rebecca S. Bigler* (Serial No. 269, 2002).

The Development of Mental Processing: Efficiency, Working Memory, and Thinking—*Andreas Demetriou, Constantinos Christou, George Spanoudis, and Maria Platsidou* (Serial No. 268, 2002).

Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Subscription prices for 2008 are: Premium Institutional: US$585 (The Americas), £417 (Rest of World). Premium Online-Only rates are also available (see below). Prices are exclusive of tax. Australian GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www.wiley.com, click on Help and follow the link through to Journal subscriptions. The Premium institutional price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.interscience.wiley.com/journals.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit www.blackwellpublishing.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (US office); +44 (0) 1865 778315 (UK office); or +65 6511 8000 (Asia Office). Subscription in 2008 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives*. Single issues from current and recent volumes are available at the current single issue price from Wiley-Blackwell Journals. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org/cd.html. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. This journal is available online. Visit www.blackwell-synergy.com to search the articles and register for table of contents e-mail alerts.

For new orders, renewals, sample copy requests, claims, changes of address and all other subscription correspondences please contact the Journals Department at your nearest Wiley-Blackwell office (address details listed above). Direct and Indirect Aggression During Childhood and Adolescence: A Meta-Analytic Review of Gender Differences, Intercorrelations, and Relations to Maladjustment

Noel A. Card
University of Arizona

Brian D. Stucky
University of North Carolina Chapel Hill

Gita M. Sawalani
University of Kansas

Todd D. Little
University of Kansas

This meta-analytic review of 148 studies on child and adolescent direct and indirect aggression examined the magnitude of gender differences, intercorrelations between forms, and associations with maladjustment. Results confirmed prior findings of gender differences (favoring boys) in direct aggression and trivial gender differences in indirect aggression. Results also indicated a substantial intercorrelation ($\bar{r} = .76$) between these forms. Despite this high intercorrelation, the 2 forms showed unique associations with maladjustment: Direct aggression is more strongly related to externalizing problems, poor peer relations, and low prosocial behavior, and indirect aggression is related to internalizing problems and *higher* prosocial behavior. Moderation of these effect sizes by method of assessment, age, gender, and several additional variables were systematically investigated.

Child and adolescent aggression has received longstanding theoretical and empirical attention. The reason for this attention is clear: Aggressive behaviors, on average, are associated with maladjustment for both aggressors (Coie & Dodge, 1998; S. Feshbach, 1970; Ladd, 2005; Parke & Slaby, 1983; cf. Hawley, Little, & Rodkin, 2007) and victims (Card, 2003; Card, Isaacs, & Hodges, 2007). Historically, research has focused on direct forms of aggression, especially acts of physical aggression. Because boys typically enact more physical aggression than girls (Hyde, 1984; Maccoby & Jacklin, 1974), less research has focused on girls' aggression. Some studies have not included girls in their samples, and even studies that included boys and girls have not always analyzed potential gender differences (Björkqvist, 1994).

In the 1980s and 1990s (e.g., Björkqvist, Lagerspetz, & Kaukiainen, 1992; Cairns, Cairns, Neckerman, Ferguson, & Gariépy, 1989; Crick, 1995; Crick & Grotpeter, 1995; Lagerspetz, Björkqvist, & Peltonen, 1988; Lancelotta & Vaughn, 1989; for earlier work, see Buss, 1961; N. D. Feshbach, 1969), researchers began considering a wider range of aggressive behaviors, including forms of aggression that are more covert or indirect in nature and aimed at damaging the target's social relations (rather than, e.g., inflicting bodily harm). These forms of aggression have been given various names, including indirect, covert, relational, and social aggression. The term *indirect aggression* was introduced by N. D. Feshbach (1969) to refer to behaviors harming a target by rejection or exclusion. Lagerspetz et al. (1988) later used this term to refer to behaviors such as gossiping, befriending others, and exclusion that do not directly confront the victim. Shortly thereafter, the term *social aggression* was used by Cairns et al. (1989) to refer to children's descriptions of manipulations in group acceptance through ostracism or character attacks. Galen and Underwood (1997) used this same term to refer to behaviors such as rejection, negative nonverbal expressions, rumor spreading, or social exclusion aimed at damaging the victim's self-esteem or social status. Crick (e.g., 1995) used the term *relational aggression* to refer to harming others through manipulation of peer relationships (e.g., threatening to terminate friendship, excluding from group).

We thank Juan Casas and Jamie Ostrov for commenting on a previous draft of this work. This work was supported in part by a National Institute of Mental Health Individual National Research Service Award (F32 MH072005) to the first author, a University of Kansas Undergraduate Research Award to the second author, and a NFGRF grant (2301779) from the University of Kansas to the fourth author.

When precisely applied, each term refers to slightly different behaviors (Xie, Cairns, & Cairns, 2005). Although the existing research lacks perfect correspondence between terminology used and operational definitions employed, the constructs converge around the common theme of behaviors that attack a victim's actual or perceived social relations with others, often (though not always) in a way that avoids direct confrontation. In practice, most researchers have accepted some blurring at the boundaries among these definitions (Archer & Coyne, 2005; Björkqvist, 2001; Underwood, Galen, & Paquette, 2001). This practice is supported by factor-analytic studies indicating two forms of aggressive behavior (e.g., Crick & Grotpeter, 1995; Grotpeter & Crick, 1996; Hart, Nelson, Robinson, Olsen, & McNeilly-Choque, 1998; Vaillancourt, Brendgen, Boivin, & Tremblay, 2003). One factor includes physical reacts such as hitting, pushing, and tripping as well as overt verbal attacks such as name calling, taunting, and threatening. The second factor includes hurtful manipulation of relationships (e.g., sabotaging the target's friendships or romantic relationships) and damaging the target's social position (e.g., spreading gossip, excluding from activities), often through indirect or covert means. In this article, we refer to these two broad forms of aggression as direct and indirect aggression, respectively, based on both historical precedence (N. D. Feshbach, 1969; Lagerspetz et al., 1988) and arguments supporting this terminology (Archer & Coyne, 2005; Björkqvist, 2001). The term *indirect aggression* is also limited in that it excludes more direct attacks on social well-being, but it is a reasonable representation of this heterogeneous class of behaviors. Therefore, we adapt an inclusive definition of these two forms, including both physical and verbal aggression within direct aggression and the various terms social, relational, covert, and indirect aggression within our consideration of indirect aggression.

Gender Differences in Direct and Indirect Aggression

Attention to these indirect forms has led to a resurgence of interest in potential gender differences in aggression. Some have argued that although boys enact more direct aggression than girls, the indirect forms of aggression may be more typical of girls than of boys (e.g., Björkqvist et al., 1992; Crick, 1997). Based on etiological explanations for aggressive behaviors, several explanations for why girls might be more indirectly aggressive than boys have been offered (Archer, 2004). One is based on sexual selection theory, suggesting that attacks aimed at girls' sexual reputations (e.g., gossip about promiscuity) and their social reputations are especially prominent in intrafemale competition (Artz, 2005). A related biological explanation is that females' lower physical strength necessitates girls' reliance on indirect means of aggression more so than boys (Björkqvist, 1994). Another explanation is based on findings that girls' peer groups are characterized by fewer, closer friendships relative to boys' more numerous, casual relationships (Maccoby, 1990, 1998), suggesting that indirect aggression is particularly hurtful among girls because it targets these relationships (Crick, Bigbee, & Howes, 1996; Galen & Underwood, 1997). Finally, explanations emphasizing socialization argue that differences in the degree to which parents and other adults discourage directly aggressive behavior of girls versus boys leads girls to use more covert forms of aggression (Underwood, 2003). Such differential socialization might further occur within children's sex-segregated peer groups (Maccoby, 1990, 1998), which provides models and reinforcements for appropriate forms of enacting aggression (e.g., indirect aggression within girls' peer groups).

Despite conceptual expectations that girls enact more indirect aggression than boys, the existing literature documenting these gender differences is inconsistent. Archer (2004) performed a meta-analytic review of 78 studies that compared indirect forms of aggression enacted by males versus females from childhood throughout adulthood. His results indicated that, averaged across age, females exhibit more indirect aggression than males when assessed using some methods (i.e., observations, peer ratings, teacher reports) but not others (e.g., peer nominations, self-reports), with the magnitude of these gender differences ranging from small to medium. Archer's results (by method of assessment) specific to childhood and adolescence did not indicate gender differences in indirect aggression, although the simultaneous disaggregation by reporting method and age may have limited the ability to detect such differences.

The first goal of the current meta-analytic review was to examine the magnitude of gender differences in both direct and indirect aggression among children and adolescents. Although this first goal partially overlaps with the previous meta-analysis by Archer (2004), the current meta-analysis extends our understanding in several ways. First, we focus more explicitly on childhood and adolescence. Second, we include more studies during this developmental period (as described below, our examination of gender differences includes 107 studies of samples younger than 18 years, whereas Archer's contained 52 studies assessing this age range), allowing for more precise results and stronger generalizations.

Third, we consider a wider range of methods in assessing aggression. Fourth, we analyze corrected effect sizes (see below) to gain a more accurate representation of true gender differences. Finally, we use random-effects models that allow greater generalization of findings than the fixed-effects models used by Archer.

In addition to examining the magnitude of gender differences in direct and indirect aggression, we evaluate several potential moderators of these differences. First, we consider age moderation. Although Archer (2004) failed to find evidence of age moderation, we expect gender differences to increase between childhood and adolescence due to (a) greater engagement in gender-typical behavior; (b) increasing time spent with peers, especially same-sex peers; (c) biological changes in puberty (e.g., greater gender differentiation in physical stature); and (d) possible increases in intrasex competition (Trivers, 1972; cf. Bjorklund & Pellegrini, 2000; Wilson & Daly, 1985). We also evaluate method of assessing aggression as a potential moderator. Expectations regarding this moderator are less clear. However, we hypothesize that adults' expectations for gender-stereotypic behavior would result in teachers and parents perceiving girls as more indirectly aggressive than boys more so than peer reports, self-reports, or observations. Although we do not have specific hypotheses, we also evaluate several additional moderators of gender differences. We consider two aspects of the context from which samples were drawn: the proportion of ethnic minorities in the sample and the country in which the study was conducted. We also evaluate moderation by the gender of the first author of the study in order to explore whether gender-linked expectations influence findings regarding gender differences. In addition, we consider whether a focus on gender in the study, operationalized by whether the term *gender* (or similar terms) appeared in the title. Finally, we consider publication status in order to evaluate potential biases in the results.

Intercorrelation Between Direct and Indirect Aggression

Although factor-analytic studies have supported the distinctiveness of indirect forms of aggression from direct forms, even a casual perusal of this literature suggests that these two forms of aggression are often highly intercorrelated. The second goal of this meta-analytic review, then, was to evaluate the magnitude of the correlation between direct and indirect aggression and to examine potential moderators of this interrelation. The magnitude of the correlation between these two forms speaks to the important issue of whether they should be viewed as different manifestations of a common underlying construct (if correlations are high) or as separate, independent constructs (if correlations are low). The magnitude of this correlation also speaks to, albeit indirectly, the potential origins of these forms: High correlations would imply common origins such as shared genetic contributions, common evolutionary functions, or common parental or peer socialization for the two forms. In contrast, modest correlations suggest differences in the origins of these two forms. Although our meta-analysis does not attempt to identify these shared versus unique antecedents, the magnitude of the association between direct and indirect forms of aggression can suggest in which direction we should look.

We consider several potential moderators of these correlations, although little prior evidence is available to suggest directions of these moderators. Against the viable alternative of no change, the two forms of aggression may become either more differentiated or more overlapping with age. On the one hand, several reasons for expecting decreasing correlations between direct and indirect aggression with age can be offered. With age, understanding of the outcomes of aggression (both rewards and consequences) and cognitive capacity to enact various forms of aggression may increase. Peer group pressure for "gender normative" forms of aggression may also increase with age. Increasing biological differences between boys and girls following puberty and increasing saliency of intrasexual competition (and the use of specific forms of aggression to achieve dominance) might also predict greater differentiation with age. Together, these possibilities suggest that older children and adolescents are more likely to enact a "preferred" form of aggression than would younger children, thus leading to a decrease in the magnitude of correlation between direct and indirect aggression with age (i.e., divergence). On the other hand, verbal skills and understanding of social dynamics increase with age (combined with the maintained capacity to enact physical aggression) making all forms available among older children. With increasing age, individuals with a propensity to behave aggressively (e.g., if a common genetic origin for aggressiveness exists) would increasingly use all available forms. This view suggests higher correlations between direct and indirect forms at higher ages (i.e., convergence). Because either possibility is plausible but prior research has not illuminated this issue, we investigate age moderation of this correlation.

Similarly, the prior literature provides little guidance to indicate whether measuring direct and indirect aggression via some sources results in different magnitudes of overlap than do other sources. Such differences, however, might be expected. For example, because trained observers should distinguish between these two forms precisely, observational measures may yield lower correlations between direct and indirect aggression than studies using other sources. In this meta-analysis, we compare the magnitudes of the correlations between direct and indirect aggression when assessed via self-, peer, teacher, and parent reports and observations.

We also examine gender moderation in the magnitude of the correlation between direct and indirect aggression. The direction of this potential moderator is likely to depend on the magnitude of any gender differences (see above). For example, if girls enact more indirect aggression than boys (whereas boys enact more direct aggression than girls), then the correlation between direct and indirect aggression may be similar for boys and girls (i.e., boys enact primarily direct aggression with some secondary indirect aggression, whereas girls enact primarily indirect aggression with some secondary direct aggression). If a gender difference in indirect aggression is not present, then these forms may be more highly intercorrelated among boys (for whom both forms are viable options) than girls (for whom direct aggression is a less viable option and therefore likely enacted by different individuals).

Finally, we systematically explore potential moderation of this intercorrelation by ethnic and national context, author gender, whether the study focused on gender, and publication status.

Associations of Direct and Indirect Aggression With Maladjustment

As noted, aggressive behaviors, on average, are associated with maladjustment. However, far less is known about the specific links that may exist between maladjustment and direct versus indirect forms of aggression. Research emerging in the past couple decades has examined these associations, but the current meta-analysis is the first to quantitatively summarize the associations of direct and indirect aggression with four indices of adjustment: internalizing problems, externalizing problems, prosocial behavior (an index of positive adjustment), and peer relations. Although these constructs represent a small sample of adjustment indices, they give a general indication of the psychosocial adjustment of directly and indirectly aggressive children.

An important question to consider regarding the distinction between direct and indirect aggression is whether these two forms *differentially* relate to maladjustment. Therefore, we examine the independent and differential magnitudes of association (defined below) of direct and indirect aggression with these four indices of adjustment to identify specific links. We expect that direct forms of aggression, which are often considered less socially acceptable than indirect forms of aggression, are more strongly linked to externalizing behavior problems, low prosocial behaviors, and poorer peer relations. In contrast, we expect indirect aggression to be more strongly linked to internalizing problems than direct aggression. The reason for this latter expectation is that aggression in general shares some antecedents with internalizing problems, such as aversive home environments, problematic peer relationships, and certain social cognitions (e.g., negative view of others). We expect that these potential links between internalizing problems and aggression would manifest primarily in the form of indirect aggression because children who suffer these internalizing problems may prefer the less risky, more covert nature of indirect forms if they are inclined to act aggressively.

The associations of direct and indirect aggression to maladjustment may also vary by age and gender. Although the empirical evidence for developmental trends is scarce (Baillargeon et al., 2007; Tremblay, 2000), some (e.g., Björkqvist, 1994) have suggested that direct aggression peaks during early childhood (this tendency actually differs for physical vs. verbal aspects of direct aggression, with the former peaking earlier than the latter). In contrast, Björkqvist (1994) suggested that indirect aggression peaks during later childhood and adolescence, paralleling the development of greater verbal abilities and social sophistication. Although this potential pattern does not imply that direct aggression is absent during adolescence or that indirect forms of aggression are not enacted by young children, it does suggests two possible directions of age moderation. First, engaging in forms of aggression that are developmentally less appropriate (i.e., direct aggression during adolescence and indirect aggression during early childhood) may be associated with greater maladjustment, perhaps because this aggression elicits harsher consequences (e.g., more severe consequences by parents and teachers and more rejection by peers). Alternatively, aggression that is developmentally normative may reflect a typical manifestation of maladjustment and therefore may be more strongly linked to maladjustment.

Gender is another potential moderator of the associations of direct and indirect aggression with adjustment. Our expectations of the direction of moderation are rooted in the concept of gender normative forms of aggression, namely, that direct aggression is normative for boys and indirect aggression is normative for girls (Crick, 1997). This concept does not imply that either form is used exclusively by either gender nor does it specify the forces that might differentially promote or inhibit these forms among one gender or the other. Nevertheless, the gender normative concept suggests two potential directions of gender moderation. First, engaging in gender nonnormative forms of aggression represents greater maladjustment and leads to greater social censure by adults or peers than does engaging in gender normative forms (Crick, 1997). This possibility would result in direct (more so than indirect) aggression being related to maladjustment among girls, whereas indirect (more so than direct) aggression would be related to maladjustment among boys. A second possibility is predicated on the existence of greater variability in gender normative than gender nonnormative aggression. This difference could lead to indirect aggression relating to maladjustment more strongly among girls, whereas boys may exhibit a pattern of direct aggression being more strongly related to maladjustment.

In addition to age and gender, we also systematically explore other moderators of these associations between the two forms of aggression and maladjustment. Specifically, we consider method of assessing aggression, sample ethnicity and nationality, author gender, whether the study title indicated a focus on gender, and publication status.

Summary of Goals

To summarize, we have three primary goals. First, we seek to examine potential gender differences in direct and indirect aggression during childhood and adolescence, a goal that overlaps with but expands upon prior reviews (Archer, 2004; Hyde, 1984; Maccoby & Jacklin, 1974). Second, we examine the magnitude of intercorrelation between direct and indirect aggression in order to determine the extent that these represent common manifestations of a single behavior (i.e., aggressiveness) versus distinct constructs. Third, we investigate the associations of direct and indirect aggression with several aspects of maladjustment, aiming especially to identify the unique, differential links each form has with maladjustment. As a secondary goal, we systematically investigate several potential moderators of these effect sizes.

Method

Selection of Studies

We obtained studies through five approaches. First, we conducted computerized literature searches of the PsycINFO, ERIC, and Proquest (for unpublished dissertations) databases using the keywords "indirect aggression," "relational aggression," "social aggression," or "covert aggression" (last search performed August 2007; we did not include terms specific to direct aggression because we wanted to identify studies with both forms, as described below). Second, we examined references cited in other articles (i.e., "backward search" procedures). Third, we asked several experts in this area to examine earlier lists of reports and suggest other studies. Fourth, we e-mailed all first authors and dissertation supervisors of otherwise obtained reports to request additional studies. Finally, we requested additional studies through the Society for Research in Child Development (SRCD) Peer Relations listserve. The latter two approaches were designed to obtain unpublished studies that might not have been obtained through other means. We chose to be lenient in our initial review of studies in order to be as inclusive as possible, so we reviewed a total of 588 journal articles, chapters, books, dissertations, and unpublished studies in selecting studies for potential inclusion.

We included studies that met three criteria. First, they presented data on both direct and indirect forms of aggression that were relevant to any of the questions of interest in this meta-analysis (i.e., gender differences, intercorrelations, associations with maladjustment). Second, the sample consisted of children younger than 18 years (i.e., adult samples were excluded). Third, the sample could be considered normative (as opposed to including only children in psychiatric or criminal settings). Using these criteria, a total of 148 independent studies presented in 165 reports, consisting of 73,498 children, were included in the meta-analyses reported here.

Coding of Studies

For all studies, we coded sample size, internal consistencies of relevant scales (for correction of unreliability), whether continuous variables were artificially dichotomized (for correction of dichotomization), and effect sizes of interest (see below). We also coded nine variables as potential moderators of effect sizes. The first of these was the method of assessing direct and indirect aggression coded as self-reports, peer nominations, peer ratings, teacher reports, parent reports, or observations. We also coded several characteristics of the sample, including the mean age of the sample, the percentage of ethnic minorities in the sample, and the country from which the sample was drawn (ultimately dichotomized into studies conducted within the United States vs. those conducted outside of the United States due to the low representation of individual countries besides the United States). When results were reported separately for boys and girls (for intercorrelations and associations with maladjustment), we coded these results both overall and by gender (to evaluate gender moderation). We also coded the gender of the first author of the study and whether the study included gender (or related terms such as *sex* or terms such as *boys* and *girls*) in the title, as these variables might be related to potential gender differences in results. To evaluate potential publication bias (described below), we coded two aspects of publication status: (a) whether the study was unpublished versus published and (b) a continuous variable of a potential hierarchy of publication quality: 1 = *unpublished, not dissertation*; 2 = *unpublished dissertation*; 3 = *published book chapter*; 4 = *published peer reviewed journal article*; and 5 = *published article in top-tier journal*, indexed as a top 20 developmental journal in impact factor according to Journal Citation Reports (e.g., *Child Development*, *Development and Psychopathology*, *Developmental Psychology*, *Journal of Abnormal Child Psychology*, *Journal of Clinical Child and Adolescent Psychology*, *Journal of Educational Psychology*, and *Journal of Experimental Child Psychology*). To assess accuracy of coding, two authors independently coded a sample of 77 studies; comparisons indicated more than 98% agreement.

We calculated effect sizes as correlations (a) of gender with each form of aggression (to evaluate gender differences), (b) between direct and indirect aggression (to evaluate intercorrelations between the two forms), or (c) of both forms of aggression with indices of psychosocial adjustment. We examined four types of adjustment indices. *Internalizing problems* included clinical or subclinical depression and anxiety. Externalizing problems included two aspects: (a) *emotional dysregulation and attention deficit hyperactivity disorder (ADHD) symptoms* such as impulsivity, frustration intolerance, tendencies to easily become angry or upset, inattention, and hyperactivity, and (b) *delinquent behaviors* such as oppositional or defiant behaviors, destruction of property, deceitfulness and theft, and rule violations. We considered these specific aspects of externalizing problems rather than a general externalizing construct to avoid overlap in behaviors that define aggression and the externalizing problem. *Prosocial behavior* included behaviors such as helping others, sharing, and cooperating. Finally, sociometric status included two aspects: *peer acceptance* (i.e., being liked by many peers) and *peer rejection* (i.e., being disliked by many peers).

Statistical Analysis

Effect size calculations. We represented most effect sizes (gender differences in direct and indirect aggression, intercorrelations between the two forms, and associations of each form of aggression with maladjustment) as Pearson correlations, r. For studies reporting results in other metrics (e.g., other effect sizes such as Cohen's d, results of significance tests such a t tests, and descriptive data such as means and standard deviations), these data were transformed to r using standard procedures (e.g., Rosenthal, 1991). Studies reporting only a significant association (at a certain p or assumed to be .05 if not otherwise stated) were given the minimum r that would achieve that level of significance given the sample size, and studies reporting only that a particular effect size was not significant (with no other information from which to compute an effect size) were assigned $r = 0$. These standard practices represent a conservative approach and may lead to slight underestimation of overall effect sizes.

In order to obtain accurate effect sizes among the constructs of interest, we corrected for two study artifacts that attenuate effect sizes, using the general equation $r_{\text{corrected}} = r/a$ (where a is the total artifactual correction, computed as the product of the following individual corrections; see Hunter & Schmidt, 2004). The first of these corrections was for unreliability of measures, in which we estimated artifactual corrections based on reported reliabilities of both variables composing the correlation, $a_{\text{reliability}} = \sqrt{\alpha_X\alpha_Y}$ (with α_x and α_Y representing the internal consistencies of variables X and Y in the correlation; Hunter & Schmidt, 2004, p. 35). For studies that did not report internal consistencies of measures, we used the mean reliability obtained from meta-analysis (Rodriguez & Maeda, 2006) of studies reporting internal consistencies ($\bar{\alpha}$s = .85 and .82 for direct and indirect aggression, respectively; full results of these analyses are available from the first author). The second correction we made was for attenuation among studies that artificially dichotomized variables used in the effect size (e.g., median or 1 *SD* splits to group participants as aggressive vs. nonaggressive). We used the artifactual correction for this dichotomization ($a_{\text{dichotomization}} = \Phi(c)/\sqrt{PQ}$; for details, see Hunter & Schmidt, 1990, 2004, p. 36) for one or both dichotomized variables comprising the correlation.

To examine the unique relations of each form of aggression to maladjustment, it was necessary to account for the magnitude of the correlation between direct and indirect aggression. To estimate the independent relation of each form of aggression (e.g., indirect aggression after controlling for direct aggression), we computed semipartial correlations (*sr*) from the (corrected) bivariate correlations of direct and indirect aggression with the adjustment variable and between direct and indirect aggression using the following formulas (Cohen & Cohen, 1983):

$$sr_{\text{direct}} = \frac{r_{\text{direct}} - r_{\text{indirect}} r_{\text{corr}}}{\sqrt{1 - r_{\text{corr}}^2}} \text{ and}$$
$$sr_{\text{indirect}} = \frac{r_{\text{indirect}} - r_{\text{direct}} r_{\text{corr}}}{\sqrt{1 - r_{\text{corr}}^2}}, \qquad (1)$$

where r_{direct} is the correlation of direct aggression to the adjustment variable, r_{indirect} is the correlation of indirect aggression to the adjustment variable, and r_{corr} is the correlation between direct and indirect aggression.

To compare the relative magnitudes of the correlations of direct versus indirect aggression with the adjustment variables, we computed a *d* score for each study representing the difference in associations (*r*s) of direct and indirect aggression to the correlate. Adapting traditional methods of comparing dependent correlation coefficients (e.g., Cohen & Cohen, 1983), the following formula was used (Card & Little, 2006):

$$d = \frac{(r_{\text{direct}} - r_{\text{indirect}})\sqrt{(n-1)(1+r_{\text{corr}})}}{\sqrt{\frac{2(n-1)}{n-1}|R| + \bar{r}(1-r_{\text{corr}})^3}} \frac{1}{\sqrt{n-3}}, \qquad (2)$$

where r_{direct} is the correlation of direct aggression to the correlate, r_{indirect} is the correlation of indirect aggression to the correlate; r_{corr} is the correlation between direct and indirect aggression, $|R| = 1 - r_{\text{direct}}^2 - r_{\text{indirect}}^2 - r_{\text{corr}}^2 + 2r_{\text{direct}} r_{\text{indirect}} r_{\text{corr}}$, $\bar{r} = (r_{\text{direct}} + r_{\text{indirect}})/2$; and n is the number of participants in study.

The semipartial correlations (*sr*) and the difference scores (*d*) both index the unique relations of direct and indirect aggression with adjustment but in different ways. The semipartial correlations indicate the direction and magnitude of the relations of each form of aggression to adjustment that are independent of the other form (specifically, the positive or negative square root of the variance in the adjustment variable that overlaps with that form of aggression only). These semipartial correlations, however, do not directly evaluate the differential relations direct and indirect forms of aggression have with the adjustment variable. This differential relation is instead captured by the difference score (*d*), which indexes the magnitude of the *difference* in the relations of each form of aggression with adjustment (but says nothing of the magnitude of association of either one of the forms of aggression with adjustment). Therefore, both the semipartial correlations and the difference scores are needed to evaluate the distinct associations direct and indirect aggression have with psychosocial adjustment.

Among studies reporting results separately for boys and girls, we were interested in whether these results differed by gender. To evaluate this potential gender moderation, we adapted traditional methods of comparing independent correlations (e.g., Cohen & Cohen, 1983) to yield the following equation:

$$d = \frac{2(Zr_{\text{boys}} - Zr_{\text{girls}})}{\left(\sqrt{\frac{1}{n_{\text{boys}}-3} + \frac{1}{n_{\text{girls}}-3}}\right)\left(n_{\text{boys}} + n_{\text{girls}} - 4\right)}, \qquad (3)$$

where Zr_{boys} is the Fisher's Z transformation of correlation for boys, Zr_{girls} is the Fisher's Z transformation of correlation for girls, n_{boys} is the number of boys in study, and n_{girls} is the number of girls in study.

This formula was used to compare the magnitude of intercorrelation between direct and indirect aggression, as well as the associations of both forms of aggression with adjustment, across gender for those studies reporting these results separately for boys and girls. In order to evaluate whether the direction and magnitude of differential associations of direct and indirect aggression with adjustment differed (i.e., was moderated) by gender, *d* scores from Equation 2 were transformed to *Zr* (for boys and girls separately), and then applied within Equation 3.

Combining and comparing effects across studies. All effect sizes were combined using weighted random-effects analyses (e.g., Hedges & Vevea, 1998). This approach was preferred because, as will be seen below, all the meta-analyses performed indicated significant heterogeneity around the mean effect sizes (i.e., fixed-effects models were not appropriate).

Before combining effect sizes, we first transformed correlation metrics (*r* and *sr*) to Fisher's Z_r (or Z_{sr}) in order to provide an approximately normally distributed metric (averaged values of Z_r and Z_{sr} were transformed back into $\bar{r}$ and $\overline{sr}$ for reporting; Rosenthal, 1991). We analyzed difference scores in their *d* metric. We averaged multiple effect sizes (Z_rs, Z_{sr}s, or *d*s) from the same study in order to yield one effect size per study (for moderator analyses, one effect size for any given level of the moderator) in order to avoid violating independence assumptions when testing significance and computing standard errors.

When averaging across multiple studies, we weighted effect sizes by an inverse variance weight using the general formula, mean ES = $\sum w\mathrm{ES}/\sum w$. Three components comprised this weight. The first component is a function of study sample size, where $w = n - 3$ for bivariate correlations; $w = n - 4$ for semipartial correlations (Hays, 1994); and $w = 1/[(4/df)(1 + (d^2/8))]$ for the differential index (Lipsey & Wilson, 2001, p. 49). The second component of this weight is an adjustment for artifact correction for the corrected effect sizes (as described by Lipsey & Wilson, 2001, pp. 110, 112). The third component of this weight is the estimated random between-study variance, τ^2 (Hedges & Vevea, 1998, pp. 491–492).

When sufficient studies existed and the overall effect sizes contained significant heterogeneity (as indexed by Q, which is distributed as χ^2 with $df = k - 1$; Lipsey & Wilson, 2001, p. 115), we systematically examined several potential moderators, including the methodology (method by which aggression was assessed), sample (sample age, gender, percentage of ethnic minorities, and country), author gender, and whether gender or similar terms appeared in the title. We also considered two publication status (dichotomous and continuous) variables as moderators in order to evaluate potential publication bias.

We evaluated categorical moderators (aggression reporter, country, first author gender, gender in title, and dichotomous publication status) using variance partitioning procedures analogous to analysis of variance (Lipsey & Wilson, 2001, pp. 135–138; Overton, 1998). Specifically, we divided heterogeneity of effect sizes (Z_rs, Z_{sr}s, or ds) among studies (Q_{total}) into within-moderator-groups (Q_{within}; e.g., among studies using teacher reports) and between-group ($Q_{\mathrm{between}} = Q_{\mathrm{total}} - \sum Q_{\mathrm{within}}$) components. This between-group heterogeneity is distributed as χ^2 (with df = number of groups − 1) under the null hypothesis that population effect sizes are equal across moderator groups. Significant between-group heterogeneity is indicative of moderation.

To test continuous moderators (i.e., sample age, percentage of ethnic minorities, and publication quality), we used procedures analogous to weighted regression (for details, see Lipsey & Wilson, 2001, pp. 138–140; Overton, 1998). Specifically, we regressed the Z_rs, Z_{sr}s, or ds from each study onto the continuous moderator, weighted by the appropriate weights described above (note that the standard errors of this weighted regression were modified according to the procedures recommended by Lipsey & Wilson, 2001, p. 140). The heterogeneity among studies accounted for by the continuous moderator, $Q_{\mathrm{regression}}$, is also distributed as χ^2 (with 1 df) under the null hypothesis that population effect sizes do not change linearly across levels of the moderator (e.g., across age). We interpreted significant relations between the moderators and the effect sizes using the effect size intercept and slope to obtain model-implied effect sizes at selected levels of the moderator (model-implied Z_rs were converted to implied rs for reporting).

As with our analyses of overall effect sizes, we modeled residual heterogeneity of effect sizes in our moderator analyses. Therefore, these analyses can be considered mixed-effects models in that the moderator variables were considered fixed, whereas effect sizes of individual studies were allowed to randomly vary (Hedges & Vevea, 1998; Overton, 1998).

Results

Before describing our results, we present general characteristics of the 148 studies included in these meta-analyses (Table 1). The studies varied considerably in terms of sample size and to a lesser extent age (with early childhood and older adolescence not well represented) and percentage of ethnic minorities in the sample (few studies had high percentages of minorities). Self-reports, peer nominations, and teacher reports were the primary methods of assessment; most studies were conducted in the United States; and most studies were published with females as first authors. Table 1 also indicates heterogeneity among studies in terms of whether the study was published (dichotomous) and publication quality.

We present the results of our meta-analyses in three parts. First, we report the magnitudes of gender differences in direct and indirect forms of aggression as well as potential moderators of these differences. Second, we investigate the intercorrelations between direct and indirect forms of aggression (and potential moderators of these intercorrelations). Third, we examine the associations of direct and indirect aggression with four indices of adjustment: internalizing problems, externalizing problems, prosocial behavior, and peer relations.

Gender Differences in Direct and Indirect Aggression

As displayed in Figure 1 (and listed in Table A1), 107 studies (consisting of 50,977 participants) reported results speaking to the magnitude of gender differences in direct and indirect aggression during childhood and adolescence. The additional studies included here but not in Archer (2004) were

predominantly published since 2000 or 2001, when the last searches for Archer's meta-analysis were performed. Table 2 summarizes the results of meta-analytic syntheses of these gender differences.

Overall, gender differences in direct aggression are generally consistent with prior reviews (e.g., Hyde, 1984; Maccoby & Jacklin, 1974). As shown in Table 2, we find significant heterogeneity among these studies in the magnitude of gender differences in direct aggression. Therefore, we conducted random-effects analyses to evaluate the typical magnitude of this gender difference and mixed-effects models when evaluating moderators. Overall, boys were more directly aggressive than girls, with an average effect that was medium in magnitude, $\bar{r} = .29$ (note that positive *r*s indicate higher levels of aggression for boys, whereas negative *r*s indicate higher levels of aggression for girls). To facilitate comparison to other meta-analyses of gender differences, this effect size is equivalent to $\bar{d} = .61$. Moderators of these effect sizes revealed several noteworthy findings. First, method of assessing direct aggression is related to the magnitude of gender differences, with parent reports and self-reports yielding the smallest gender differences, whereas peer reports (nominations or ratings) and observations yield the largest differences (see Table 2 for full details). The percentage of ethnic minorities in samples also relates to the magnitude of gender differences in direct aggression, such that smaller differences are found with increasing percentages of ethnic minorities. Furthermore, studies with the word *gender* (or similar terms) in the title yield slightly larger gender differences in direct aggression, although studies without this term in their title still exhibit significant, moderate magnitude differences. The mean age of the sample, country from which the

Note. Significant differences among reporters from follow-up comparisons are denoted by different alphabetic subscripts. CI = confidence interval.

[a] Due to low representation of individual countries outside of the United States, this variable was dichotomized to studies conducted within versus outside of the United States. [b] Dichotomous variable of whether the word *gender* (or similar terms such as *sex* or *boys* and *girls*) was in the title.

*$p < .05$. **$p < .01$. ***$p < .001$.

sample was drawn, and first author gender are not significantly associated with magnitudes of gender differences in direct aggression. In order to compare gender differences in physical versus verbal aspects of direct aggression, we conducted post hoc analyses of 27 studies that reported gender differences separately for these two aspects. Results indicate that gender differences are stronger for physical ($\bar{r} = .34$, equivalent $\bar{d} = .73$) than verbal ($\bar{r} = .19$, equivalent $\bar{d} = .38$) expressions of direct aggression.

We also find significant heterogeneity across studies for gender differences in indirect aggression. Similar to Archer's (2004) findings, our (random effects) results indicate a negligible, but statistically different from zero, average gender difference, with girls exhibiting more indirect aggression than boys, $\bar{r} = -.03$ (equivalent $\bar{d} = -.06$). As with direct aggression, this gender difference in indirect aggression varies by reporter. Specifically, parent and teacher reports yield gender differences of girls being higher than boys, whereas self-reports yield a slightly higher level for boys than girls. Other reports are not significantly different from zero (see Table 2 for details). However, the magnitude of these gender differences in indirect aggression is trivial regardless of reporter. Age, percentage of ethnic minorities in sample, country of sample, first author gender, and whether gender appeared in the title do not moderate gender differences in indirect aggression.

Intercorrelations Between Direct and Indirect Aggression

Figure 2 and Table A2 show the 98 studies reporting associations between direct and indirect aggression. As shown in Table 3, we find significant heterogeneity among these effect sizes. The random-effects average corrected correlation between the two forms of aggression is $\bar{r}$ = .76 (even uncorrected effect sizes representing correlations as found in studies is high, $\bar{r}$ = .60; results involving uncorrected effect sizes mirror those presented here and are available from the first author). Although separable (i.e., the confidence interval of this correlation does not include 1.0), direct and indirect aggression are clearly strongly correlated.

Given the heterogeneity of effect sizes across studies, we examined moderators of this association (Table 3). Method of assessment significantly moderates this association, such that observational methods yield considerably lower correlations than other methods. Direct and indirect aggression are also more strongly correlated among boys than girls, as well as with increasing percentages of ethnic minorities in the samples. The mean age of the sample, country from which the sample was drawn, the gender of the first author of the study, and whether the source included the term *gender* in the title do not significantly moderate the magnitude of correlations between direct and indirect aggression.

Associations of Direct and Indirect Aggression With Maladjustment

We next consider the magnitudes of associations of direct and indirect aggression with four aspects of adjustment: internalizing problems, externalizing problems, prosocial behavior, and peer relations. We first present average bivariate correlations of each form of aggression with the adjustment index, then average independent (i.e., semipartial) correlations for each form and the differential association (i.e., *d*) that direct versus indirect aggression has with the adjustment index. As before, we systematically evaluate potential moderation of these effects.

Figure 3. Stem-and-leaf plot of associations of direct and indirect aggression with internalizing problems.

Internalizing problems. Results of 26 studies (Figure 3 and Table A3) indicate significant heterogeneity in the bivariate, semipartial, and differential associations of direct and indirect aggression with internalizing problems (Table 4). Only indirect aggression exhibits significant bivariate and unique (i.e., semipartial) associations with internalizing problems as well as significant differential association between the two forms with internalizing problems. Moderator analyses reveal three differences. The first difference is by reporter, such that parent, teacher, and self-reported direct and indirect aggression exhibit the strongest associations with internalizing problems, although aggression reporter does not significantly moderate the differential association of direct versus indirect aggression with internalizing problems. The second significant moderator is the percentage of ethnic minorities in the sample, such that samples with higher percentages of ethnic minorities exhibit higher differential associations between direct versus indirect aggression. This effect is explained by nonsignificant trends of indirect aggression having stronger positive associations and direct aggression having stronger negative associations with higher percentages of minorities. The third significant moderator is whether the title of the work included *gender* or similar terms. Studies with *gender* in the title show stronger differential associations of the two forms of aggression with internalizing problems; specifically, studies with this term have positive unique (semipartial) associations of indirect aggression to internalizing problems and unique links of direct aggression to *lower* internalizing problems. Sample age, participant gender, country in which the study was conducted, and first author gender (with one exception) do not consistently moderate associations of direct or indirect aggression with internalizing problems.

Externalizing problems. As mentioned, we report results regarding two aspects of externalizing problems: emotional dysregulation/ADHD-type symptoms and delinquency/conduct problems. This focus on specific aspects of externalizing problems allows us to avoid a potential confound that would exist if we had considered general externalizing problems, which are often measured using items that also assess aggression. Of the 18 studies considering emotional dysregulation and ADHD-type symptoms, 12 specifically assessed symptoms of ADHD, 5 assessed ease of anger or frustration, and 1 assessed a more general emotional reactivity. Of the 14 studies of delinquency/conduct problems, 10 used established measures of conduct problems (e.g., Child Behavior Checklist conduct problems subscale) and 4 used specific behavioral descriptions. The scales used to assess each type of externalizing problems were generally well-established measures designed to specifically measure these constructs. For instance, the measures from Achenbach's system (i.e., Child Behavior Checklist, Youth Self Report, and Teacher Report Form), used in several of these studies, explicitly distinguish aggression from both delinquent behaviors (McMahon & Estes, 1997) and ADHD symptoms (Barkley, 1997). For these reasons, it is reasonable to consider associations of direct and indirect aggression with these conceptually distinct aspects of externalizing problems.

The 18 studies investigating associations with emotional dysregulation and ADHD-type symptoms (see left portion of Figure 4 and upper portion of Table A4) exhibit significant heterogeneity in their results (Table 5). Random-effects combination of these results indicates that both direct and indirect forms of aggression have large bivariate correlations to these symptoms. However, direct aggression is more strongly associated than indirect aggression (differential *d* in Table 5), and only direct aggression is uniquely related to these symptoms (semipartial correlations in Table 5). The source of aggression measurement moderates these associations, such that (a) parent-reported direct aggression is most strongly linked to these symptoms and (b) both parent and teacher reports exhibit the largest differential associations with direct being more strongly associated than indirect. We also find that studies with the term *gender* in the title exhibit greater differential

*$p < .05$. ** $p < .01$. *** $p < .001$.

associations (with direct being more strongly associated than indirect) than studies without this term. However, the source of this moderation (i.e., studies with this term have stronger unique associations for direct aggression, whereas studies without this term had stronger unique associations for indirect aggression) is not readily explainable. Participant age and gender, percentage of ethnic minorities in sample, and author gender do not significantly moderate any of the associations (bivariate, semipartial, or differential) of these forms of aggression with emotional dysregulation/ADHD-type symptoms.

The results of 14 studies reporting associations of direct and indirect aggression with delinquency and conduct problems (shown in the right of Figure 4 and bottom of Table A4) are also significantly heterogeneous (Table 6). Random-effects meta-analyses indicate that both direct and indirect aggression have large bivariate correlations with these problems and that both are uniquely associated with these problems. The differential index indicates that direct is more strongly related to these problems than indirect aggression, as evidenced by the medium unique effect of direct in contrast to the small unique effect of indirect. These results are moderated by method of assessing aggression (Table 6). However, these reporter moderator effects are due primarily to the single study using parent-reported direct and indirect aggression

Figure 4. Stem-and-leaf plot of associations of direct and indirect aggression with externalizing problems.

(Tiet, Wasserman, Loeber, McReynolds, & Miller, 2001). If this study is removed, there is no evidence of reporter moderation. The only other moderator of these results is the percentage of ethnic minorities in samples. Here, indirect aggression exhibits increasingly stronger (bivariate and semipartial) associations with conduct problems in samples with increasing percentages of ethnic minorities (this effect also results in smaller differentials between direct and indirect aggression in samples with higher percentages of ethnic minorities). Participant age and gender, country of sample origin, author gender, and whether *gender* appeared in the title do not moderate these results.

Prosocial behavior. Associations of direct and indirect aggression with prosocial behavior are significantly heterogeneous across the 31 studies reporting these effects (Table 7, Figure 5, and Table A5). Random-effects meta-analyses indicate that both direct and indirect aggression have negative bivariate correlations with prosocial behavior (Table 7). However, the differential association (*d*) is significant, and this difference can be seen clearly in the unique (semipartial) associations: Direct aggression is uniquely related to *low* prosocial behavior, whereas indirect aggression is uniquely related to *high* prosocial behavior.

Several features moderate these associations of direct and indirect aggression with prosocial behavior (Table 7). Age moderates the differential between direct and indirect aggression, such that the strongest differences (of direct aggression being associated with low prosocial behavior, whereas indirect aggression is associated with high prosocial behavior) are evident at younger ages. Method of assessing aggression consistently moderates these associations (Table 7). The country from which the sample was drawn also moderates effects, such that indirect aggression only exhibits unique (semipartial) associations to *high* prosocial behavior in the United States; samples drawn from other countries yield a negative semipartial correlation between indirect aggression and prosocial behavior.

Peer relations. Two aspects of peer relations have been examined with respect to direct and indirect aggression in a sufficient number of studies to allow meta-analytic examination: peer acceptance and peer rejection.

The 23 studies (see left portion of Figure 6 and top of Table A6) reporting associations of direct and indirect aggression with peer acceptance are significantly heterogeneous (Table 8). Both forms of aggression have small to moderate bivariate associations with low peer acceptance, but this association differs by form, and only direct aggression is uniquely associated with low peer acceptance. Moderator analyses yield only two findings. First, indirect aggression more strongly relates to low peer acceptance with increasing percentages of ethnic minorities in samples (this trend also results in changes in the direct vs.

[a] See Equation 3 and accompanying text for description of how gender moderation was evaluated. [b] Due to low representation of individual countries outside of the United States, this variable was dichotomized to studies conducted within versus outside of the United States. [c] Dichotomous variable of whether the word *gender* (or similar terms such as *sex* or *boys* and *girls*) was in title.

$^*p < .05$. $^{**}p < .01$. $^{***}p < .001$.

indirect differential with ethnic composition; Table 8). Second, we find a similar moderator effect for whether the term *gender* appears in the title, such that stronger associations of indirect aggression with low peer acceptance are found for studies with this term. Other moderators (i.e., sample age, method of assessing aggression, gender, country, and author gender) do not moderate links of direct and indirect aggression with peer acceptance.

The 22 studies (see right of Figure 6 and bottom of Table A6) reporting associations of direct and indirect aggression with peer rejection are also heterogeneous (Table 9). Both forms exhibit significant bivariate and semipartial associations with peer rejection, although this link is stronger for direct than indirect aggression. We also find several moderators of these effects. Method of assessing aggression moderates some effects (Table 9) such that parent-, teacher-, and peer-reported aggression (direct and indirect) are more strongly linked than observations of aggression. Moderation by country is also evident for the bivariate (but not semipartial or differential) associations, such that both direct and indirect aggression are more strongly related to peer rejection within the United States than in other countries. Finally, female first authors find significant unique (semipartial) associations of indirect aggression with peer rejection, whereas male first authors do not find this effect

(resulting also in male first authors finding differential effects between direct and indirect aggression that are not found by female first authors).

Publication Bias

Publication bias is a threat to any meta-analytic review (for overviews, see Begg, 1994; Rothstein, Sutton, & Borenstein, 2005). The threat of this bias is that unpublished studies, relative to published studies, are more likely to have nonsignificant results (or otherwise smaller effects) and less likely to be included in a meta-analytic review. The result of this possibility is that the conclusions drawn from this biased sample are themselves biased, specifically with estimated effect sizes being larger than those that actually exist. The threat of publication bias can be managed in a number of ways. The most important way is to obtain unpublished studies, which we have done by including unpublished dissertations and requesting unpublished studies from researchers in the field. However, even this does not ensure that publication bias is not evident. Therefore, we statistically evaluate the potential presence of publication bias in three ways.

Differences by publication status. The first way we evaluated potential publication bias was to test whether obtained results differ by publication status. As mentioned above, we considered publication

status in terms of both a dichotomous unpublished versus published variable as well as a more continuous publication quality variable. As summarized in the first column of Table 10, we compared unpublished versus published studies as moderators of each of the 33 effect sizes considered in this review. We similarly evaluated publication quality (unpublished studies other than dissertations, dissertation, chapter, journal article, and article in top-tier journal) as a continuous moderator of these effects (second column of Table 10).

Of these 66 analyses, 11 are significant. Examination of Table 10 shows that these significant moderators involve associations of direct and indirect aggression with prosocial behavior and peer rejection. For prosocial behavior, bivariate and semipartial associations of direct aggression and bivariate associations of indirect aggression are moderated by both the dichotomous and the continuous publication status variable (the latter also moderates the differential association). However, the direction of moderation in each case is such that unpublished/low-status studies exhibit *stronger* associations with low prosocial behavior (i.e., more negative) than published/high-status studies. Similar directions are evident for peer rejection, in which the bivariate correlations for both direct and indirect aggression are greater for unpublished/low-status studies than for published/high-status

studies. Given the general lack of moderation by publication status, as well as the unexpected direction of those that do emerge, these analyses fail to indicate a threat of publication bias.

Sample size–effect size correlations. A second way we tested for publication bias is by examining correlations between sample sizes and effect sizes in studies. If publication bias—in the form of nonsignificant results being less likely to be included in analyses—exists, then one would expect a correlation between these two variables (a negative correlation if the overall effect size is positive and a positive correlation if the overall effect size is negative). The reason for this correlation would be that studies with small samples would need larger effect sizes to obtain statistical significance. Therefore, only those that happened to obtain these large effects would be published (or otherwise included in the meta-analysis), whereas those that found smaller effects would be unpublished/excluded from the meta-analysis. In contrast, studies with large sample sizes would be more likely to obtain significance regardless of effect size (assuming that the population effect size itself is nonzero). Thus, a correlation between study sample size and effect size can indicate the presence of publication bias.

We computed correlations between sample sizes and effect sizes for each of the 33 effects in our review. As can be seen in Table 10 (third column), the majority of these correlations are not significant. In fact, only two related sample size/effect size correlations are significant: (a) the semipartial correlation of direct aggression with peer rejection and (b) the differential association of direct versus indirect aggression with peer rejection. Visual inspection of funnel plots (available from first author upon request) suggests that two studies (Johnson, 2003; Nelson, Robinson, & Hart, 2005) primarily contributed to these correlations.

Failsafe numbers. A third method of evaluating the potential impact of publication bias is to compute failsafe numbers (Becker, 2005; Rosenthal, 1979). Failsafe numbers indicate the number of studies with average effect sizes equal to zero that would have to exist to conclude nonsignificant effects. This number is meant to index the number of studies with effect sizes of zero that could have been excluded from the meta-analysis before the conclusions of significance would be invalidated. If this failsafe number is small, then the findings are not robust because the possibility of just a small number of excluded studies could change the conclusions of the meta-analysis. However, if the number is large, then one can be confident that the findings of the review are robust even if a large number (i.e., the failsafe number) of studies, all with an average effect size of zero, were inadvertently excluded from the meta-analysis. A common rule of thumb applied to determining whether the failsafe number is adequately large is $N_{\text{min}} = 5k + 10$ (where k is the number of studies currently in meta-analysis; Becker, 2005; Rosenthal, 1979).

We computed Rosenthal's (1979) failsafe N for all effect sizes that were statistically significant in our review (it is not relevant to compute this number for nonsignificant effects because addition of null findings would not change the nonsignificant result). We used the formula: $N = k(Z_s/Z_\alpha)^2 - k$, where k is the number of studies in the meta-analysis, Z_s is the summed significance level of studies in the meta-analysis ($Z_s = \sum Z_i/\sqrt{k}$), and Z_α is the critical Z value at $\alpha = .05$ (Becker, 2005; Rosenthal, 1979). As can be seen in Table 10 (fourth and fifth columns), the failsafe numbers exceed recommended minimums in all but one case (the failsafe number for the semipartial correlation of indirect aggression with prosocial behavior does not exceed this recommended minimum).

The results of all three approaches to evaluating publication bias converge to the general conclusion that publication bias is not a likely threat to the results of this review.

Discussion

Although developmental researchers have long understood the importance of studying childhood aggression, only recently has attention focused on the indirect forms this aggression can take. This meta-analysis synthesizes the available evidence to address three topics important to this focus: gender differences in direct and indirect aggression, the intercorrelation of these two forms, and the associations these two forms of aggression have with adjustment. Below, we discuss the findings of this meta-analysis, identify shortcomings of both this meta-analysis and the extant empirical literature, and suggest directions for future research.

Findings From the Current Meta-Analysis

Results regarding overall gender differences are consistent with prior reviews of the literature: Boys tend to enact more direct aggression than girls, but there is little gender difference in indirect aggression (our finding that girls enact more indirect aggression than boys was statistically significant but trivial in magnitude). Given the number of studies included here and in Archer's (2004) meta-analyses, the support for negligible gender differences in indirect aggression seems conclusive. This conclusion of trivial gender differences in indirect aggression challenges common portrayals of this form being more commonly enacted by girls than boys (e.g., Björkqvist

et al., 1992; Crick, 1997). Instead, indirect aggression can be considered a form that is more equitably enacted by girls and boys than direct aggression (although the medium magnitude of gender differences in direct aggression should alert us to the fact that direct aggression is also a problem among girls). This gender similarity in indirect aggression generally held across methods of assessing aggression. Although reporter moderation was found, such that girls are viewed by teachers and parents as more indirectly aggressive than boys, and boys view themselves as more indirectly aggressive than do girls (no gender differences emerged for peer nominations or ratings or for observations), these differences were generally small.

The trivial gender difference in indirect aggression was also consistent across age, ethnicity, and country (i.e., no evidence of moderation). The failure to find age trends in gender differences is interesting in that it runs counter to expectations that socializing forces exacerbate gender differences with development (e.g., Baillargeon et al., 2007). We conclude that the general pattern is of *similarities* rather than differences among boys' and girls' use of indirect aggression. This conclusion raises questions regarding *why* the misperception that girls are more indirectly aggressive than boys is so pervasive. Evidence suggests that early-developing gender schemas guide biases in processing social information consistent with this misconception (Giles & Heyman, 2005). Recent popular accounts of indirect aggression among girls also likely contributes to a dualistic focus on gender differences (rather than similarities; Horn, 2004) among teachers, parents, and even researchers. More broadly, our conclusion of gender similarity in indirect aggression supports arguments that studying aggression among both genders, rather than focusing exclusively on boys, is an important endeavor (Pepler, Madsen, Webster, & Levene, 2005; Putallaz & Bierman, 2004; Underwood, 2003).

The second goal of this review was to examine the magnitude of intercorrelation between direct and indirect aggression. On average, this correlation was very high, suggesting that these two forms are overlapping manifestations of childhood aggression. At the same time, this correlation is not perfect, supporting factor-analytic studies showing the separability of these two constructs (Björkqvist et al., 1992; Crick & Grotpeter, 1995; Grotpeter & Crick, 1996; Hart et al., 1998; Macgowan, Nash, & Fraser, 2002; Vaillancourt et al., 2003). The average (corrected) correlation (.76) implies that about half (57%) of the variance in these

two forms overlaps, whereas the remaining variance is unique. Therefore, researchers should consider both the overlapping and the unique aspects of direct and indirect aggression in future work and examining the antecedents of both aggressiveness in general and direct or indirect aggression specifically is clearly warranted.

The overlap between direct and indirect aggression varied across several moderators (i.e., age, information source, and gender). Observations yield more distinct measures of direct versus indirect aggression than do other reports. Here, distinguishing an aggressive act as direct versus indirect is not always clear for untrained reporters (e.g., teachers, peers), and the cleanest measures are obtained via trained observers. Alternatively, it may be more difficult to observe indirect forms of aggression during the limited sampling periods often used, so the truly high correlation between forms is missed when using this methodology. Given that observations of aggression are difficult and time consuming, future research should evaluate whether the high overlap that exists among other sources of information is due to fuzziness in classifying acts and, if so, how researchers can obtain clearer assessments using other reporters. Although our review indicates which methods yield lower or higher correlations between direct and indirect aggression, it does not address which method yields

[a] Comparison of unpublished versus published studies. Values that represent $Q_{(1)}$ are distributed as $\chi^2_{(1)}$ under the null hypothesis of no difference between unpublished and published studies. [b] Regression of effect sizes onto continuous publication quality variable. Values that represent $Q_{regression}$ are distributed as $\chi^2_{(1)}$ under the null hypothesis of no linear trend of effect sizes across publication quality. B_{ES} represents linear change in effect sizes with increasing publication quality. [c] Correlation between study sample sizes and effect sizes; expected to be zero when there is no publication bias. [d] Rosenthal's (1979) failsafe *N*, which represents the number of excluded studies with $ES = 0$ that would need to exist before the effect size would be reduced to nonsignificance. [e] Rosenthal's (1979) recommended minimum failsafe number, $5k + 10$. This number is used to interpret Rosenthal's failsafe *N*. If Rosenthal's failsafe *N* is larger than this number, results can be considered robust to the threat of excluded studies yielding a nonsignificant effect.
$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

the "true" overlap between them. Perceptions of individuals not specifically trained to distinguish direct and indirect aggression (i.e., self-reports, peers, teachers) may be "blurred," resulting in inflated estimates of this overlap. Alternatively, the limited sampling of aggressive acts witnessed in observational studies may deflate the true overlap of children's tendencies to enact both forms of aggression. Multimethod research (using multiple sources of information in different contexts) may help answer this question. Further research on factors that influence perceptions of behaviors and individuals as directly and indirectly aggressive (e.g., Card, Hodges, Little, & Hawley, 2005; Neese, 1997; Ostrov, Crick, & Keating, 2005) will also aid in understanding the sources of this correlation.

Our results also indicate greater overlap of direct and indirect aggression among boys than girls. The combination of gender differences favoring boys' use of direct aggression and the trivial gender differences in indirect aggression (discussed above) suggests that both direct and indirect types are common in boys' behavioral repertoire. Because either form of aggression is common among boys, they may view both as possible ways to aggress against potential victims. Therefore, boys who enact one form of aggression may be inclined to also enact other forms of aggression, more so than for girls. The underlying reason for this gender moderation, however, is unclear. For example, biological or social forces may jointly promote both forms of aggression among boys, but one form or the other among girls. We might also ask whether these differences are veridical or a function of differential measurement processes across gender.

Arguably, the most important set of findings from this meta-analysis are the associations with maladjustment. Our findings indicate that direct and indirect aggression differentially relate to various aspect of maladjustment. Specifically, and consistent with our expectations, direct aggression is more strongly, and uniquely, associated with emotional dysregulation, conduct problems, low peer acceptance, and peer rejection (although indirect aggression also had unique associations with conduct problems and peer rejection). In contrast, indirect aggression is more strongly and uniquely associated with internalizing problems, perhaps reflecting that children with such problems are more willing to engage in these indirect, covert means of aggression than direct, confrontational forms. Interestingly, direct aggression exhibits a unique association with low prosocial behavior, whereas indirect aggression has a unique association with *high* prosocial behavior. Children using indirect aggression, which often requires the involvement of other peers (e.g., to aid in exclusion or rumor spreading), must also use prosocial skills to garner the support and assistance of others. Given the high correlation between direct and indirect aggression, most individual studies would not have sufficient power to identify these independent and differential associations. Here, the statistical power of meta-analytically combining results from multiple studies elucidates these unique links between the form of aggression and the maladjustment.

We found some evidence of moderation of these links, although caution should be exercised in drawing conclusions given the potential confounds among moderators among the limited number of studies considered (Lipsey, 2003). Method of assessing aggression was a common moderator with parent, teacher, and peer reports (nominations and ratings) of aggression having the strongest associations with maladjustment. On the one hand, observable aggression consistently enacted may be a strong reflection of maladjustment. On the other, these observers may be attuned to children's maladjustment, which makes them more aware of (or biased in their perceptions of) children's aggressive behavior. Further studies using multiple informants of both forms of aggression and adjustment would help clarify these possibilities.

Interestingly, we found no evidence of age or gender moderation. Although one must be cautious not to over interpret null findings, the absence of age differences suggests that the associations we found generally hold across childhood and adolescence. In other words, we have no reason to believe that either form of aggression is *only* linked to maladjustment during certain periods of development (countering our expectations regarding age normative or non-normative forms being differentially related to maladjustment). The absence of gender moderation of these effects is particularly informative in that it directly counters arguments that so-called gender nonnormative forms of aggression should be related to greater maladjustment (Crick, 1997). The lack of support for this hypothesis makes sense if one considers the trivial magnitude of gender differences in indirect aggression—this form is no more normative for one gender than the other given that boys and girls enact roughly equal levels of indirect aggression.

Limitations in Our Knowledge and Directions for Future Research

An inherent limitation of this study, as with all meta-analyses, is that the quality of conclusions must rely on the literature available. That is, a central concern in any meta-analysis is that the conclusions are only valid to the extent to which the included studies represent the population of research. Our reliance on random-effects (and mixed-effects) models allows for greater generalizability of findings (more so than if we had relied on fixed-effects models; Hedges & Vevea, 1998; Overton, 1998). Nevertheless, these models still assume that the included studies are a random sampling of the population of studies; to the extent that they are not, our results may be biased. Along these lines, two particular limits of this meta-analytic review merit consideration.

First, our review considered only studies investigating both direct and indirect forms of aggression. Although this limited sampling met our goal of comparing these two forms, it does raise questions of whether our findings can be generalized to either form individually. We identified 13 studies that investigated the effects considered in this review using indirect aggression only (i.e., not assessing or reporting on direct aggression). Supplemental analyses indicated that including these additional studies do not alter any of the conclusions reached here (i.e., tests of main effects and moderators yield identical patterns of significance and virtually identical effect sizes). More difficult to evaluate is whether inclusion of the thousands of studies investigating direct aggression only (until recently, the only form of aggression considered) would have affected our conclusions regarding direct aggression. We also performed supplemental analyses in which we included a small number of these studies and did not find any evidence that these studies changed our results. These supplemental analyses provide evidence that our sample of studies of indirect *and* direct aggression can be generalized to the population of studies measuring indirect *or* direct aggression. Nevertheless, it is possible that the large body of research investigating only direct aggression differs from those included in our review, so appropriate caution should be placed in generalizing these results.

A second consideration is whether our obtained sample of studies was less likely to include some findings than others (e.g., nonsignificant results). This threat, commonly called the file drawer problem (Rosenthal, 1979), is that researchers' file drawers are filled with studies of nonsignificant (or otherwise different) results. This threat is also considered within the general term of *publication bias* to reflect the possibility that nonsignificant or otherwise unacceptable results are less likely to be published (and therefore less likely to be included in meta-analyses) than studies finding significant or commonly accepted results. Although this threat can never be ruled out, we believe that it is unlikely to have biased our results for several reasons. First, our search procedures included several ways of locating unpublished studies (i.e., searching dissertation databases, soliciting unpublished studies from researchers in the field). Second, our analyses of publication biases yielded little support that unpublished studies produced different effect sizes than published studies or that there was censoring of low effect sizes among smaller studies. Third, failsafe numbers indicated that an enormous number of studies with null results would have to exist to invalidate our results. In short, we view it as unlikely file drawers are teeming with enough studies discrepant from those included so as to invalidate our results.

A more viable limitation of our sample of studies is the adequacy of testing moderators of effect sizes. In contrast to the ample body of research from which to analyze main effects, analysis of moderators of these effects (e.g., method of assessing aggression, age, gender) were often hampered by incomplete coverage across levels of these moderators. Moreover, other aspects of the studies may have accounted for these moderator effects. For example, the method of assessing aggression is confounded by the context in which the aggression might occur (e.g., observational measures are necessarily limited to the context of observation, teacher and peer reports capture primarily in-school aggression, parent reports might capture more aggression in the home or neighborhood, and self-reports might be nonspecific to context). Similarly, the moderators examined here might themselves be confounded (e.g., researchers tend to rely more on teacher or parent reports among younger children but self- and peer reports among older children and adolescents). The question of whether reporter, age, gender, or contextual features were the "true" moderators, or simply correlated with other, unmeasured study features, is difficult to answer within a meta-analysis (Lipsey, 2003). We therefore urge caution in interpreting these moderator results, and encourage future primary work to include wider age ranges, multiple reports of aggression in multiple contexts, systematically evaluate gender moderation, and compare results across cultures and nations in order to fully evaluate these moderating effects.

Our review of the extant literature has also identified some important limitations in this area of research. First, it is critical to consider the contexts in which most studies in our review measured aggression: Most used samples drawn from schools; therefore, many of the conclusions of this meta-analysis refer primarily to aggression within the school context. Furthermore, the primary literature suffers from both a lack of variability and inadequacy in reporting important contextual features, such as the size of groups in which children interact, the gender composition of these groups, the familiarity of individuals within and between these groups, and the settings (e.g., playground, classroom) and activities (e.g., structured vs. unstructured) in which aggression occurs. Future studies should closely consider, and compare, these contextual features.

A substantial limitation in our meta-analysis and the majority of research reviewed is the reliance on concurrent data. This problem is especially relevant to our understanding of the associations of direct and indirect aggression with maladjustment. As such, our analyses speak to the magnitude of association but say nothing about the direction of influence. Each aspect of maladjustment that we considered could be conceptualized as an antecedent or a consequence of direct and indirect aggression or simply as a correlation arising from common third-variable causes. Unfortunately, longitudinal investigations that evaluate these directions of influence are rare and those that do exist are so varied in terms of time span and other methodological features that meaningful meta-analytic combination is not yet possible. We strongly urge further experimental and longitudinal research using well-planned time spans (i.e., days or years, depending on presumed time span of effects), appropriate analytic strategies (at a minimum, controlling for initial levels of the presumed consequence), and wider sampling of ages and measurement strategies within these longitudinal investigations (Card & Little, 2007).

Finally, our meta-analytic review focused on the presence and magnitude of associations but did not evaluate the source of these associations. This criticism can also be leveled at most studies within the field. In addition to asking *whether* such associations exist, it is also important to ask *why* such associations exist. As indicated, longitudinal research begins to get at this question. However, a complete answer must recognize the mediating mechanisms among these effects, with emphasis on the shared versus unique mechanisms of direct versus indirect aggression. Similarly, it is important to understand when or *under what conditions* these associations exist (i.e., moderating processes). Although our analyses provided some evidence of these moderators, more work in the form of primary studies is needed to better understand the associations documented in this review.

Conclusions

Despite these limitations, this meta-analytic review does much to organize the existing literature so as to draw conclusions and guide future work. This work expands prior reviews of gender differences in aggression and is the first to examine (a) the intercorrelation between direct and indirect forms and (b) the associations these two forms have with maladjustment. In contrast to prior reviews showing that boys enact more direct aggression than girls (Hyde, 1984; Maccoby & Jacklin, 1974), our results (replicating those of Archer, 2004) generally demonstrate an absence of meaningful gender differences in indirect aggression. Although it can be argued that some methods of assessing indirect aggression yield some evidence of gender differences (also found by Archer, 2004), the magnitudes of these gender differences are uniformly small. We conclude that indirect aggression is *not* a "female form" of aggression.

Our finding that direct and indirect aggression shares about half of their variance has two implications. First, it highlights the need to consider commonalities between the two forms. Clearly, there are causes that explain children's aggression irrespective of form, and we should not lose sight of these commonalities in our quest to understand the differences. At the same time, there are differences, which are evident through the imperfect correlation between these two forms and our findings that direct and indirect aggression differentially relate to several aspects of maladjustment.

This meta-analytic review synthesizes the existing research on direct and indirect aggression during childhood and adolescence. This synthesis has resolved inconsistencies and misconceptions in the literature to reveal important information regarding gender similarities and differences, the commonality yet separability of these two forms, and their unique associations with maladjustment. However, the greater value of this work is in pointing to directions for future research. Clearly, research on these two forms of aggression has taken us well beyond the historic, narrow focus on boys' direct aggression. Just as clearly, more research on the indirect forms of aggression, among both boys and girls, is needed. This research should diverge from much of the prior work, however, to consider both the similarities and the differences in direct and indirect aggression and in recognizing that both forms are enacted by—and have similar correlates with maladjustment for—both genders.

					Weighted random-effects average:			.29	−.03

Note. Effect sizes for gender differences are in the metric of Pearson's correlation (*r*) for comparability to other effect sizes in this report. Gender is coded so that positive correlations represent boys being more aggressive than girls, whereas negative correlations represent girls being more aggressive than boys. M = male; F = female.

[a] Publication status was coded as: 1 = *unpublished, not dissertation*; 2 = *unpublished dissertation*; 3 = *published book chapter*; 4 = *published peer reviewed journal article*; and 5 = *published article in top-tier journal* (see text for details).
